A thorough history may not only elicit symptom inconsistencies in the present illness, but may also reveal a record of inexplicable or recurrent bouts of illness associated with life events. A history of chronic abdominal pain that occurs only on school days, a history of somatic complaints associated with stressful social events, or documentation of abdominal surgery with equivocal findings should raise suspicion that the current problem represents conversion. A list of the diagnostic criteria for conversion symptoms appears in Box 237-6. No single criterion can be confirmatory, and each patient who has a conversion symptom may not display every criterion listed. However, a conversion symptom cannot be diagnosed solely based on negative physical and laboratory findings; it is not a diagnosis of exclusion.

## DIFFERENTIAL DIAGNOSIS

Other psychosomatic disorders at times may be confused with conversion symptoms. Patients exhibiting hypochondriasis, a common entity, especially in adolescents, view their symptoms with extreme concern. None of the apparent indifference seen in patients who have conversion symptoms exists. Patients who have conversion symptoms often seem relieved when an organic cause is considered; patients who have hypochondriasis become more concerned if an organic diagnosis is suggested because they suspect and fear a serious or fatal disease. However, neither type of patient is reassured more than transiently by being informed that he or she has no disease.

Malingering is an uncommon problem in adolescents, except in institutionalized adolescents or those who

### BOX 237-4 Case Report

During a routine physical examination, Jeff, a 14-year-old, mentioned that he experienced "migraine headaches," which seemed to be focused "behind my left eye" and occurred approximately once a month. Jeff's mother attached more importance to the symptoms than did Jeff. Initially, exploration of the family history proved unremarkable. Persistent questioning about stress led the mother to mention almost parenthetically that she had recently been diagnosed as having multiple sclerosis. She felt that the case was mild and, therefore, had not told Jeff and her other children directly about the diagnosis, although she sensed that the children knew. Her initial symptom that precipitated the diagnosis of multiple sclerosis was temporary loss of vision in her left eye.

### BOX 237-5 Case Report

Terry, a 15-year-old girl, recently had been treated for otitis media, which was characterized by pain and some dizziness. After the ear seemed adequately healed, her dizziness persisted. By Terry's physician encouraging her to discuss her daily schedule, the fact that she was under significant academic pressure became apparent, having recently transferred to an extremely competitive private school. In addition, extracurricular pressures were heavy, including her fervent commitment to gymnastics and her hope to achieve professional status. On further questioning, Terry related that she had had dizzy spells in past years just before competitions.

### BOX 237-6 Criteria for Diagnosis of Conversion Symptoms

- The symptom has symbolic meaning to the patient.
- The patient frequently exhibits characteristic interpersonal behaviors.
- Symptoms are often reported in a characteristically dramatic style.
- The symptom helps patients cope with their environment (*secondary gain*). Health issues and symptoms frequently are used in family communication.
- Symptoms occur at times of stress.
- The symptom has a model.
- History and physical findings often are inconsistent with anatomic and physiologic concepts.

From Prazar G. Conversion reactions in adolescents. *Pediatr Rev.* 1987;8: 279–286.

are in restrictive situations (eg, military service). Malingering may even be regarded as an appropriate means of avoiding threatening or unpleasant circumstances. Attempts to feign illness often are naive, especially in younger patients. As Engel states, malingerers exhibit “an intense need to be nurtured or suffer.” Many of these individuals appear to be accident prone and may submit to painful procedures readily and without objection. Malingering adolescents are aloof and hostile to the physician; thus, discovery of their deception often is delayed. In contrast, patients who have conversion symptoms are often appropriately fearful of procedures and may appear charming and garrulous with the physician. Malingerers and patients who have conversion symptoms are similar in that their parents may have an unconscious psychological need to have their children be ill and, therefore, may reinforce their children’s symptoms.

Somatic delusions are symptoms of psychosis and usually are not confused with conversion symptoms. Other signs of severe mental illness are usually present, such as an inability to relate to peers, visual or auditory hallucinations, and stereotypical behaviors. Furthermore, the symptoms described sometimes are intermittent and often extremely bizarre. For example, patients who have somatic delusions may express the conviction that their heart is shriveling or that something is wrong with the blood that is running from the head to the leg.

Psychophysiologic symptoms may occur when conversion symptoms have failed to dissipate anxiety. Thus, continuing anxiety activates biologic systems (especially the autonomic nervous system), resulting in physiologic changes such as tachycardia, hyperperistalsis, and vasoconstriction. A patient’s cognizance of these changes is exhibited by palpitations, diarrhea, and sweating. In this situation, the symptom itself has no organic symbolic meaning and results from a reaction to actual body changes. Therefore, psychophysiologic symptoms can occur when conversion symptoms have failed. Similarly, conversion symptoms can replace psychophysiologic symptoms.

## CARE OF THE CHILD OR ADOLESCENT WHO HAS CONVERSION SYMPTOMS

Children and adolescents who have conversion symptoms are seen most often initially, and eventually are treated, by pediatricians or other primary care physicians. Families see this course of action as appropriate because the obvious aspect of the problem is physical. They typically will accept a diagnosis of conversion only from a medical professional they consider an expert in physical disease. Nevertheless, when physicians undertake a case of suspected conversion, their interviewing acumen and sensitivity to the patient’s feelings are paramount. The initial interaction between the physician and the patient is crucial to the degree of success achieved in dealing with a conversion symptom. In essence, treatment begins before a definitive diagnosis is made. Some considerations involved in the initial evaluation of patients suspected of having conversion symptoms appear in Box 237-7.

The physician should advise the patient and family that the cause of any disorder involves both physical and emotional factors. As Schmitt states, the family should be told that “everyone’s body has a certain physical way of responding to emotional stress.” Similarly, every individual has an emotional response to physical stress. Simple examples should be given (eg, most people have learned that headaches often are intensified when they are upset). If the physician communicates an appreciation of the role of emotions in physical disease, then the family may volunteer information more readily about psychosocial functioning. Furthermore, an eventual diagnosis involving emotional aspects may be more acceptable because the family has been prepared for the possibility. Focusing only on a strictly physical diagnosis intimates to the parents that psychological involvement is unlikely, unimportant, and improbable. Turning to psychological issues after all physical tests prove unremarkable implies to parents that this approach was chosen as a last resort because the physician was unable to ascertain an organic cause. A concurrent physical–psychological diagnostic approach not only prepares the physician to consider the problem with some psychotherapeutic intent, but may also save the family time and money because multiple laboratory tests can often be avoided.

After the evaluation has been completed, the physician must develop a treatment plan. Before embarking on this venture, the physician must be satisfied with the completeness of the medical evaluation. Common sense should dictate when the physician thinks that further organic tests will be futile. The patient and family can often sense a physician’s uncertainty, especially if the family is averse to accepting a psychologic diagnosis. Therefore, a prudent step would be to ask the family what additional tests they might expect to have performed and what other diagnoses they may have considered. Involvement of the patient and family in this diagnostic process

### BOX 237-7 Important Considerations in the Initial Evaluation of Patients Suspected of Having Conversion Symptoms

From the outset, the parents and patient should be told that “everyone’s body has a certain physical way of responding to emotional stress”. The parents and patient should be encouraged to suggest diagnostic tests that they may want performed and to suggest possible diagnoses for consideration by the physician.

The parents and patient should understand that the symptom may persist, but that the goal is to help maintain normal daily functioning in school and with peers. The parents and patient should understand that referral to a psychiatrically trained professional may be necessary if progress is not made in coping with the symptom.

Modified from Prazar G. Conversion reactions in adolescents. *Pediatr Rev.* 1987;8:279–286.

frequently dissipates anxiety and allows eventual psychological counseling.

Although patients who have conversion symptoms are suggestible, reassurance that the symptom will go away rarely is effective and also does not contribute to a psychological investigation of the symptom. On the contrary, suggesting that the symptom will persist allows time to work out a therapeutic relationship with the patient and sometimes has a paradoxical effect. Because the symptom is unlikely to disappear after 2 or 3 visits, the patient will retrospectively view the physician's suggestion as sound. Trust in the physician will be reinforced, and the patient may be more comfortable communicating information about feelings. Anxiolytic medications may reduce attendant anxiety transiently in some cases of conversion symptoms; however, using medication as the sole therapy rarely results in lasting improvement. Because medication does not relieve the underlying conflict responsible for the symptom, another symptom eventually may appear. Furthermore, a risk that the medication's side effects may become the model for new conversion symptoms—or that new symptoms may be confused with side effects—does exist.

At the conclusion of the evaluation, the number of anticipated follow-up sessions should be discussed with the family. The number of sessions should be flexible so that it can be renegotiated if needed. Follow-up sessions with the teenager can usually be limited to 15 to 20 minutes every 2 to 4 weeks. More frequent visits may be necessary if symptoms interfere with school attendance, peer relationships, or family functioning. During follow-up sessions, the youth should be encouraged to talk about daily life (eg, school, friends, family, and dating). If the youth volunteers information about recurrence of the symptom, then the physician should inquire about events that were transpiring concurrently when the symptom occurred and how the youth felt about these events. In this way, the physician can help the patient become reacquainted with how daily events and feelings are related. Keeping a symptom diary may be helpful: The patient records when the symptom occurred and what was happening at the time the symptom began. Such a record may illustrate to the patient the association of the symptom with feelings or emotionally charged life events.

When physicians feel comfortable acting as both therapist and provider of acute medical care, occasions may arise when the youth has a new physical symptom or complaint that requires attention. If the physician suspects a physical illness that is unrelated to the conversion symptom, whatever evaluation that is indicated must be performed, including a full or partial physical examination. However, an overzealous search for disease should be avoided. Treatment goals need to be realistic. Conversion symptoms seldom disappear completely. However, patients often acquire increased coping skills so that their daily functioning is unimpaired, and dependence on secondary gain is minimized.

For physicians with sufficient expertise, follow-up visits with parents should take place every 4 to 6 weeks. Such meetings should serve to elicit persistent or new

concerns that parents may have about their child or teenager's progress and should be used to assess the parents' reaction to continuing complaints. The physician should emphasize the validity of the youth's concerns so that misconceptions about the symptom being faked are dispelled. Furthermore, positive reinforcement needs to be offered so that parents think they are doing what is best for their child. Selected follow-up sessions with the parents should include the child. Not only do such family meetings demonstrate to the patient that confidentiality of individual sessions is not being violated, but they also offer the physician an opportunity to observe parent-child interaction. These observations may provide an important index to the effectiveness of ongoing therapy.

## REFERRAL

Referral to mental health professionals is indicated if symptoms continue to interfere with the patient's daily activities or functioning or when the physician or school personnel think that the symptoms have not diminished. School officials can provide valuable information about the effect of the conversion symptom on school functioning and peer interaction. Referral is indicated if the family thinks that inadequate progress has been made after an agreed-on duration of therapy.

Referral also is indicated if the patient's symptom creates uncomfortable feelings in the pediatrician. Situations involving sexually suggestive adolescent behavior in association with a conversion symptom may create feelings in the pediatrician that can prevent effective intervention. Assuming that a pediatrician can treat all psychological and medical problems adequately is unrealistic. Cognizance of one's own limitations is an important professional attribute. Another situation requiring referral involves the patient or family member who is a social acquaintance or a relative of the pediatrician. Dealing with the emotional problems of friends' or relatives' children is inappropriate. Obtaining personal details of family or sexual functioning is often indicated in the evaluation and may jeopardize the social relationship. Conversely, failure or hesitancy to obtain appropriate data may jeopardize subsequent resolution of the problem.

In all cases when referral is suggested, parental and patient compliance with the referral is improved if the possibility has been mentioned as a contingency early in the evaluation. The pediatrician should always help families understand that seeing a psychiatrically trained professional does not connote *craziness*. Rather, the pediatrician may suggest that a mental health professional might help because a physician or professional trained in mental health can help patients understand feelings about prolonged or unusual symptoms better than most pediatricians. The physician should recommend a specific counselor rather than offering a list of suggested counselors. Before the name of the counselor is given to the family, the physician should verify that the counselor feels comfortable with the referral and has time available to see the patient.

After the referral is made, continued pediatrician contact with the family concerning the conversion

### BOX 237-8 Indications for Referral of Patients Who Have Conversion Symptoms

- The symptom continues to interfere with daily functioning (school attendance, participation in extracurricular activities, involvement with peers).
- Parents and patient think that no progress is being made in dealing with the symptom.
- The physician feels uncomfortable with the patient's symptom or behavior (eg, patients exhibiting sexually suggestive behavior).
- The patient's family includes a social friend or relative of the physician.

From Prazar G. Conversion reactions in adolescents. *Pediatr Rev.* 1987;8: 279–286.

symptom promotes adherence with the therapy. Indications for referring patients who have conversion symptoms are listed in Box 237-8.

The prognosis for patients who have conversion reactions is unknown. In a report of 74 children who had psychogenic pain, many patients were judged to be improved after several years regardless of whether professional intervention took place. In a 7-year follow-up of patients hospitalized with conversion, 23 of 41 patients no longer experienced their presenting physical symptom, were free of underlying stress, and had experienced no symptom substitution or new associated complaint. Patients who have conversion symptoms, indeed, may have an encouraging future. On the other hand, in some patients, adolescent conversion symptoms mark the beginning of a lifelong course of conversion illness.

### SUMMARY

Conversion reactions represent an emotionally charged issue not only literally for the adolescent but also figuratively for the physician, because patients displaying such symptoms often elicit a wide range of emotions from their physician. The physician's emotional response results from the frustration in dealing with such difficult patients. Patients have feelings about their symptoms. An evaluation of any complaint should involve inquiry into aspects of the patient's family, school attendance and performance, and peer relationships. A better understanding of the patient's baseline emotional functioning can be achieved in this way. The physician must advise both parents and patient that having feelings about symptoms is acceptable. Both family and patient may be much more accepting of primary emotional involvement if permission for expressing feelings is given early in the physician–patient relationship. The diagnosis of a conversion reaction should never be one of exclusion and should follow specific diagnostic criteria.

Care of the patient who has a conversion reaction involves establishing a renegotiable number of regular visits, encouraging the patient to discuss daily activities and interrelated feelings, meeting with parents regularly to provide them with emotional support

and counseling, and knowing that palliation rather than a cure may be the end goal. When the physician feels uncomfortable treating a patient who has a conversion reaction, or when ongoing follow-up care seems to have made no progress in reducing the symptoms, the patient should be referred to a mental health professional. However, referral should not end the physician's contact with the patient because ongoing physician interest may improve patient adherence with the referral source and may increase the physician's ability to resume responsibility later for the patient's care. The patient who has a conversion symptom usually will not outgrow it in the short term. Such patients severely tax the primary care physician's diagnostic and therapeutic acumen. However, the physician who respects the involvement of emotions with symptoms can help patients who have conversion symptoms cope with their disorders.

### Chapter 238

## CYSTIC AND SOLID MASSES OF THE FACE AND NECK

Neil E. Herendeen, MD; Peter Szilagyi, MD, MPH

The causes of neck masses range from common inflamed lymph nodes and cysts to rare neoplasms. An orderly approach to the workup and management of a neck mass is, therefore, needed. The most practical approach involves differentiating the anatomic location of the mass into lateral neck masses versus midline neck masses and determining the exact anatomic position of the mass. Localizing a lateral neck mass further

into either the anterior cervical triangle (anterior to the sternocleidomastoid muscle) or the posterior cervical triangle is helpful.

## DEFINITIONS

Masses in the neck can be classified into 2 broad categories—cystic lesions and solid masses. Cystic lesions are either congenital cysts or vascular malformations; however, traumatic hematomas and abscesses may seem to be cystic. Solid neck masses usually consist of inflammatory lymph nodes or, rarely, neoplastic lesions. In general, a complete history and thorough physical examination will lead to the correct diagnosis. Carefully chosen laboratory tests or imaging studies then confirm the diagnosis.

## DIFFERENTIAL DIAGNOSIS

When evaluating neck masses, the primary care physician (PCP) should be familiar with key anatomic structures of the neck. Because most neck masses encountered by pediatricians are lymph nodes and not cysts, understanding the location of the different groups of lymph nodes within the anterior and posterior anatomic triangles of the neck is crucial. Figure 238-1 shows the location of the major groups of lymph nodes, the sternocleidomastoid muscle, and the typical locations of the congenital cysts encountered most commonly.

## EVALUATION

### History

The physician should determine whether the neck mass was observed at birth, whether it has increased or decreased in size, whether it has changed color, and whether the lesion has drained or opened. Knowing the age at onset may help, because lymph nodes greater than 1 cm in diameter rarely appear at birth,

whereas many congenital cysts are noted in the newborn period. Some congenital cysts, however, may not be noted until childhood or beyond and are detected only when they become infected.

The history of pain or tenderness is important. Congenital cysts are nontender unless they become infected. Inflamed lymph nodes are tender and painful. Pain during eating suggests parotid gland involvement. History of fever, other systemic symptoms such as loss of weight, and fatigue may need to be elicited while considering the possibilities of infectious processes and malignancies.

### Physical Examination

The first step in the physical examination is to determine whether abnormalities exist in other parts of the body, such as other cysts, lymphadenopathy, hepatosplenomegaly, skin lesions, or signs of infection. The exact anatomic location of the neck mass must be determined, and the physician should note whether the mass is in the typical location of a lymph node (see Figure 238-1). The consistency, color, and firmness of the mass should be noted, as well as the presence of tenderness. The size of the mass should be measured.

Midline masses are usually associated with a thyroid abnormality. Masses that move with swallowing or with tongue protrusion suggest a thyroglossal duct cyst; these lesions may be tethered to the foramen cecum by the thyroglossal duct remnant. A mass along the anterior edge of the sternocleidomastoid muscle that moves with swallowing or that has a sinus opening to the surface of the overlying skin is likely to be a branchial cleft cyst. Both cysts and benign lymph nodes are freely mobile; malignant lesions are more likely to be fixed to underlying structures.

Rapidly growing, painless neck masses are worrisome because they might be neoplastic. Additional signs associated with a neoplastic process include fixation of the mass to subcutaneous tissue, firm consistency, size greater than 3 cm, and presence of constitutional symptoms. Supraclavicular nodes are the most likely neck mass to be malignant and should always be investigated.

### Laboratory Evaluation

A complete blood count and blood culture can sometimes be helpful in assessing a tender, erythematous mass. Thyroid hormone levels should be measured if the thyroid gland is enlarged.

### Imaging Studies

Ultrasound or magnetic resonance imaging (MRI) scan can determine whether the mass is cystic or solid or whether it extends to deeper structures within the neck. Technetium scans can confirm the presence of thyroid tissue before a surgical procedure.

## CONGENITAL CYSTS

The following lesions account for most congenital masses of the head and neck. The major challenges in the differential diagnosis involve differentiating congenital masses from lymph nodes and determining the type of congenital lesion.

**Figure 238-1** Common locations for cystic (orange circles) and lymph nodes (blue circles) of the face and neck.

### Thyroglossal Duct Cysts

Thyroglossal duct cysts account for more than 70% of congenital cysts of the neck, branchial cleft cysts for more than 20%, and vascular malformations and other lesions for 4% to 5%.

Thyroglossal duct cysts result from failure of the embryologic thyroglossal duct to degenerate during the fifth week of gestation, leaving a fistula, sinus tract, or cyst at the midline of the neck just below the hyoid bone. Thyroglossal duct cysts are not often detected at birth and are usually noted first after the age of 2 years. They may initially show as inflamed, tender masses. When not infected, they are smooth, firm, mobile, and nontender and move upward with tongue protrusion or with swallowing. The differential diagnosis includes sebaceous cysts, epidermal cysts, submandibular lymph nodes, and lipomas. Unless normal thyroid tissue is palpable, the physician needs to confirm the presence of the thyroid gland by ultrasonography or technetium scan, because what may seem to be a thyroglossal duct cyst may actually be an ectopic thyroid gland, and its removal would leave the child dependent on thyroid hormone supplementation for life. Because the likelihood of infection is high, thyroglossal duct cysts should be removed surgically.

### Branchial Cleft Cysts

Branchial cleft cysts are congenital remnants of the lateral 4 branchial pouches and clefts. Most branchial cleft cysts arise from the second cleft or pharyngeal pouch. They appear as a small dimple or opening anterior to the middle portion of the sternocleidomastoid muscle. The cyst is nontender, firm, and mobile, and is located just under the skin. A small sinus, which occasionally drains fluid to the surface of the overlying skin, may be present, and a long fistulous tract may extend from it to the tonsil bed. Branchial cleft cysts without sinuses are often unnoticed until later childhood when they become infected. Infected cysts can easily be confused with lymphadenitis. Other lesions included in the differential diagnosis are sternocleidomastoid muscle masses associated with torticollis, small lymphatic malformations, epidermoid cysts, neurofibromas, lipomas, and an ectopic thyroid gland. Treatment involves surgical removal of the cyst and fistula.

### Lymphatic Malformations

Lymphatic malformations are congenital, avascular masses derived from congenital obstruction of lymphatic vessels. They are generally multilocular, fluid-filled, soft, compressible, painless masses located in the posterior triangle just behind the sternocleidomastoid muscle and in the supraclavicular fossa. Lymphatic malformations can usually be transilluminated. These masses may grow rapidly because of accumulation of lymph and can reach an enormous size, compressing important structures and obstructing the airway. Although the diagnosis is usually obvious during the physical examination, smaller lymphatic malformations may resemble hemangiomas or other cysts. Ultrasound will reveal fluid and multiple cystic components, confirming the diagnosis. Macrocystic lesions can usually be dramatically reduced with injection sclerotherapy. Surgical removal

is usually employed only if there are microcysts that can't be sclerosed. Lymphatic malformations occur infrequently in the axilla, on the trunk, or on the extremities; in older children, when they occur within the subcutaneous tissues, they may be mistaken for a lipoma or a hemangioma.

### Epidermoid Cysts

Epidermoid cysts are relatively common masses that may arise from an embryologic or fusional defect. They are usually located at midline on the face, most often at the level of the eyebrows. These small cysts feel doughy and smooth and contain sebaceous material and sometimes even hair, cartilage, or bone. One-third of these cysts are present at birth; the remaining two-thirds appear by school age. Because these cysts may become infected and may form deep tracts, surgical excision is indicated.

### Preauricular Cysts and Sinuses

Preauricular cysts and sinuses are the most common anomalies arising from an embryologic fusion failure of precursor tissues that develop into the external ear. The sinuses are pinhole-size pits that are usually located anterior to the helix (see Figure 238-1), and they may contain a short sinus tract. Preauricular cysts often are bilateral. These sinuses and cysts are inherited in an autosomal-dominant manner, with incomplete penetrance, and are found more commonly in blacks than in whites. They are a far more common cause of preauricular lesions than are first branchial cleft cysts and sinuses, which are located in the same area. Because preauricular cysts and sinuses may become infected, elective surgical removal is preferred. Hearing deficits may be associated with these lesions, but their prevalence is unknown.

### DEEP HEMANGIOMAS

Deep hemangiomas are vascular lesions within the subcutaneous tissues that may appear in any part of the body and may be difficult to differentiate from congenital cysts.

They are often noted in the newborn period and enlarge, sometimes rapidly, during the first year of life. Deep hemangiomas are less firm, more diffuse, and more easily compressible than cystic masses (except for lymphatic malformations). Unlike lymphatic malformations, deep hemangiomas do not transilluminate, and the skin overlying these vascular lesions is often bluish. Deep hemangiomas often begin to increase in size during the first few months of life, but usually regress spontaneously by school age. For masses that compress vital structures or have the potential to cause severe disfigurement, oral propranolol can be used to hasten involution.

### SOLID NECK MASSES

Cervical lymph nodes are often palpable in healthy children and can be distinguished by their location (see Figure 238-1), size, shape, consistency, and mobility. Enlarged cervical lymph nodes (>1 cm) should be defined further by their association with surrounding nodes or generalized adenopathy, the presence of an infection of the head or pharynx, and localized signs

of inflammation and erythema. Cervical adenitis typically develops as a swollen, tender, erythematous mass in a child who has a fever. *Staphylococcus aureus* and *Streptococcus pyogenes* account for 80% of acute unilateral cervical adenitis and usually respond to oral antibiotics such as a penicillin or cephalosporin. Lymph node aspiration is usually reserved for patients whose disease does not respond to initial therapy. Incision and drainage is an option for masses that become fluctuant. Some of the various causes of cervical lymphadenopathy include viral infections of the upper respiratory tract, bacterial infections, human immunodeficiency virus (HIV) infection, Kawasaki disease, and systemic disorders such as systemic lupus erythematosus, juvenile idiopathic arthritis, sarcoidosis, and histoplasmosis. Chronic inflammation of the lymph nodes can be seen with infections such as cat-scratch disease (see Chapter 215, Animal and Human Bites), atypical mycobacterium, and toxoplasmosis.

Malignant tumors are often found as a single supraclavicular mass or as multiple or matted masses crossing into both the anterior and the posterior triangles. More than 25% of children who have malignancies have a tumor of the head or neck. The most common neck malignancies include Hodgkin and non-Hodgkin lymphoma, neuroblastoma, lymphosarcoma, rhabdomyosarcoma, fibrosarcoma, and thyroid tumors.

## MANAGEMENT

All congenital cysts and masses should be monitored closely by the PCP. Acute bacterial infections of cysts should be treated with systemic antibiotics. Patients who have thyroglossal duct cysts, branchial cleft cysts, or epidermal cysts should be referred to a surgeon who is experienced at excising these congenital lesions. Lymphatic malformations can often be sclerosed if necessary, thus avoiding surgical removal.

Elective surgery before an infection develops is preferable because excision of an entire sinus tract, fistula, or embryologic connection is more difficult after an infection. Many PCPs and surgeons prefer to delay surgery until the child is beyond infancy and can better tolerate the procedure. For patients who have thyroglossal duct cysts, a PCP or surgeon should confirm the presence of normal thyroid tissue by ultrasound or by a technetium scan. Hemangiomas can be observed without referral unless they begin to impinge on vital structures. Hemangiomas that interfere with physiologic functions (blocking the vision, interfering with eating, among other functions) may be treated with propranolol or glucocorticoid steroids, or referred to a surgeon for management.

For children who have enlarged cervical lymph nodes and evidence of infection, the antibiotic therapy should improve the condition within 7 days; the condition should resolve completely over the next few weeks. If the adenopathy is persistent, if inflammation is not present, and if any characteristics are worrisome (eg, size >3 cm, immobile, associated with systemic symptoms, in an abnormal location), then the child should be evaluated further and treated for the underlying cause of an enlarged lymph node if one can be identified, or otherwise monitored closely until the lymphadenopathy resolves.

## WHEN TO REFER

- Cysts or tracts that are congenital (all congenital cysts or tracts should be removed)
- Mass that does not resolve with antibiotic therapy ( $\geq 2$  weeks)
- Mass in the thyroid gland
- Mass in the parotid gland
- Rapidly enlarging mass ( $> 3$  cm)
- Mass that is fixed or lymph nodes that are matted
- Mass in a concerning area (eg, supraclavicular)
- Abnormal chest radiograph
- When systemic signs and symptoms (eg, fever, weight loss, easy fatigability, hepatosplenomegaly) are present

## WHEN TO ADMIT

- Infected mass that is unresponsive to oral antibiotics
- Worrisome mass requiring immediate intervention and imaging
- Mass compromises the airway

## Chapter 239 CYSTIC FIBROSIS

Donna Beth Willey-Courand, MD; Bruce C. Marshall, MD, MMM

Cystic fibrosis (CF) is an autosomal-recessive disease involving multiple organs, especially the pancreas and lungs. When the disease was first described in 1938, the median survival for children with CF was less

than 1 year. Today, the predicted median survival for people with CF in the United States is approaching 40 years of age, demonstrating how dramatically the face of this disease has changed over a relatively short period.

## INCIDENCE

Cystic fibrosis occurs with a frequency of approximately 1 in 3,600 live births in the white population, in whom it is the most common inherited lethal disease. The incidence is 1 in 15,000 in blacks and 1 in 6,500 in Hispanics. Because the carrier state is asymptomatic, the birth of a child with CF is often the first knowledge parents have that they carry a mutation.

## PATHOPHYSIOLOGIC FEATURES

The CF gene consists of 250 kilobase-pairs located on the long arm of chromosome 7. It codes for a 1,480-amino acid glycoprotein product known as the cystic fibrosis transmembrane-conductance regulator (CFTR). Currently, more than 1,000 mutations of the CFTR gene have been found that alter CFTR structure and function and result in the development of CF. The most common mutation in North America and Europe, accounting for approximately 70% of alleles in the United States, is a deletion of 3 base pairs, resulting in the deletion of phenylalanine (F) at position 508 (F508del). Although the CFTR genotype is highly predictive of pancreatic function, it is less predictive of the pulmonary disease. Recent evidence suggests that gene modifiers, as well as environmental factors, contribute to the pulmonary phenotype.

The CFTR glycoprotein is located in numerous organs throughout the body, including the lungs, upper respiratory tract, sweat glands, pancreas, intestines, liver, and reproductive tract. CFTR is a cyclic adenosine monophosphate-regulated membrane-channel protein that secretes chloride and other ions across the cell membrane and regulates several other proteins, including an epithelial sodium channel. Reduction or absence of CFTR activity results in impaired movement of chloride across the cell membrane and increased reabsorption of sodium. Because passive reabsorption of water molecules follows that of sodium, hydration of secretions is reduced in the affected organs. In CF airways, this results in a decreased periciliary fluid layer volume and height; and because sufficient fluid is critical for proper ciliary function, patients with CF experience impaired mucociliary clearance. CFTR also facilitates  $\text{HCO}_3^-$  transport across the epithelial membrane, and loss of CFTR function results in a decrease in airway surface liquid pH and reduced antimicrobial activity. Other cellular effects of CFTR loss, such as changes to pH and fatty acid ratios, have pleiotropic results at the tissue level, including altered pH of glandular secretions and an exaggerated inflammatory response.

## CLINICAL MANIFESTATIONS

### Infection

Ineffective mucociliary clearance and other changes predispose CF airways to infection. *Staphylococcus aureus* and *Haemophilus influenzae* are important

bacterial pathogens, but *Pseudomonas aeruginosa* has become the primary pathogen in this disease. Initially, nonmucoid environmental strains of *P. aeruginosa* are detected in patients. However, the CF airway environment leads to a transition to mucoidy and to a biofilm mode of growth, which results in an accelerated rate of decline in lung function.

### Lower Respiratory Tract

Despite the chronic nature of the airway infection, ongoing neutrophilic inflammation is typical. DNA released from dying neutrophils increases the viscosity of the airway secretions. Impaired ciliary function and tenacious secretions lead to stasis, and the distal airways become plugged. Bronchoscopic studies of infants with CF reveal that even if the children appear clinically well, neutrophil and proinflammatory (interleukin-8) mediator levels are increased. Chest computed tomographic (CT) scans also show that structural changes in the lung can often be detected despite normal pulmonary function. The battle in the lungs of patients with CF begins very early in life and may progress unnoticed.

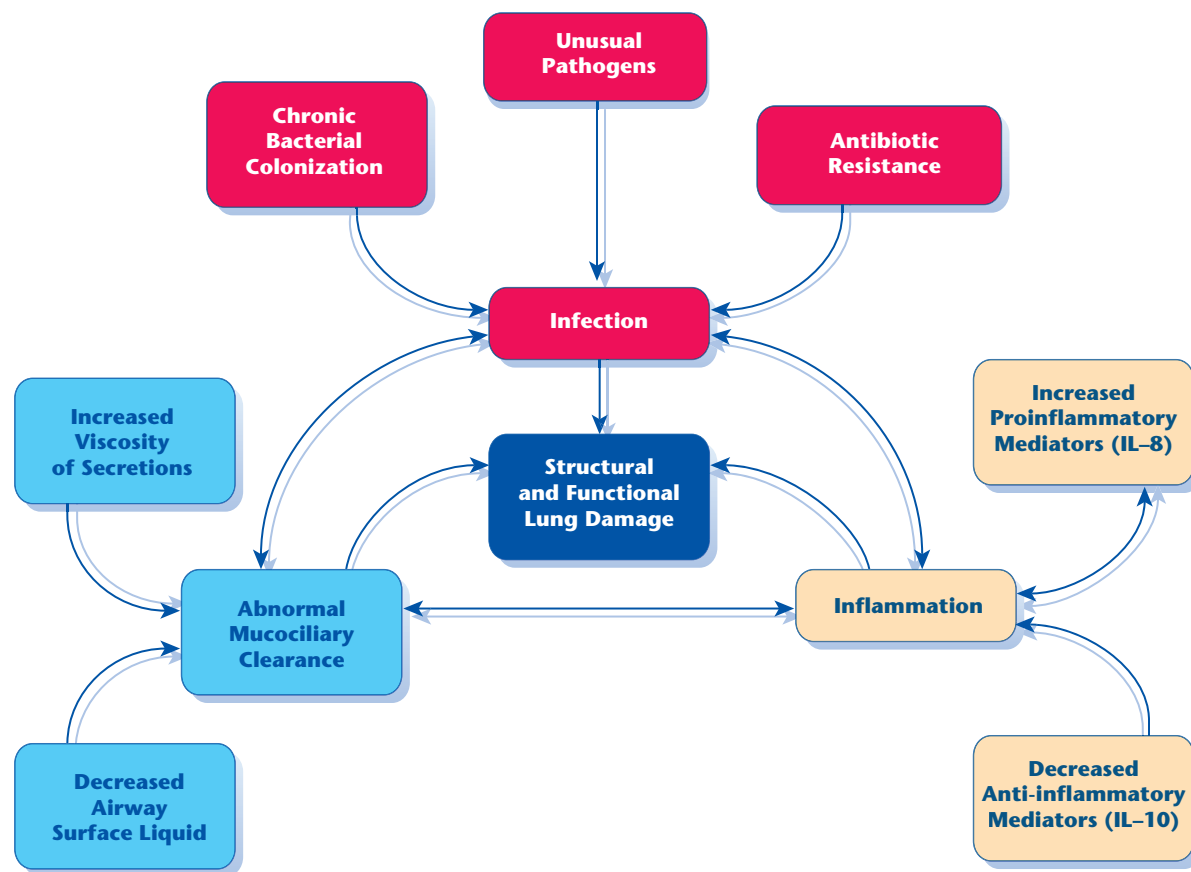

A cycle of infection and inflammation (Figure 239-1) develops in the lungs of patients with CF, typically punctuated by acute exacerbations. This process eventually damages and destroys the airways, leading to bronchiectasis. Complications such as hemoptysis and pneumothorax may appear as the lung disease progresses. Death most commonly results from respiratory failure and cor pulmonale caused by recurrent or chronic pulmonary infections.

### Upper Respiratory Tract

The same pathophysiologic mechanism also affects the upper respiratory tract. Even a moderate loss of CFTR activity can adversely affect the sinuses, and children with CF are predisposed to recurrent and chronic sinusitis despite normal nasal mucociliary clearance. Hypoplasia of the sinuses is a common finding. Nasal polyps are also common, especially among individuals who are homozygous for F508del CFTR. The etiology of polyposis is unknown, although it does not appear to be associated with allergies. Polyps may obstruct the nasal passages and contribute to the development of sinusitis.

### Gastrointestinal Tract

CFTR is also located throughout the gastrointestinal tract in the pancreas, intestines, and liver. In the pancreas, abnormal electrolyte secretion from the epithelial cells lining the pancreatic ducts results in dehydration of the ductal secretions and blockage of the pancreatic ducts. Destruction of the pancreatic acini occurs, and pancreatic enzyme secretion is significantly decreased. Bicarbonate secretion from the pancreatic ducts is also reduced, which further decreases the effectiveness of the pancreatic enzymes. This condition, known as pancreatic insufficiency (PI), occurs in 85% to 90% of patients with CF. In general, good correlation exists between pancreatic status and genotype. Patients with 2 severe mutations, such as F508del/F508del, have PI, and patients with 1 or 2 mild mutations are much more likely to have pancreatic

**Figure 239-1** The evolution of cystic fibrosis-related lung disease, the end result of a multifactorial process involving abnormal mucociliary clearance, inflammation, and infection. IL, interleukin.

sufficiency, although they are at increased risk for pancreatitis. Individuals who have pancreatic sufficiency generally have better clinical outcomes than patients with PI. PI results in the malabsorption of fats, proteins, carbohydrates, and the fat-soluble vitamins A, D, E, and K. Children with PI have difficulty growing and gaining weight. Optimization of nutritional status is essential to maintaining pulmonary function (Figure 239-2).

Patients with PI are at risk for intestinal dysfunction. Intestinal manifestations of CF may be present even before birth. Fetal ultrasound may reveal hyperechoic bowel, suggesting retention of mucous material in the intestine. Approximately 10% of infants with CF present with meconium ileus, an obstruction of the distal ileum with thick, inspissated, poorly hydrated material. Clinically, newborns exhibit delayed passage of meconium, abdominal distention, and a bubbly or granular-appearing material in the region of the terminal ileum on radiograph. Volvulus, intestinal atresia, and meconium peritonitis may occur as complications of meconium ileus. In older children and adults, poor hydration of intestinal contents, decreased secretion of pancreatic enzymes, inspissated intestinal secretions, and fecal stasis may produce a partial or complete obstruction of the small or large intestine. This distal intestinal obstruction syndrome (DIOS) may develop as an acute event or may occur chronically. Symptoms

include vomiting, abdominal distention, crampy abdominal pain, and, possibly, a mass in the abdomen, most often in the right lower quadrant. Patients may continue to pass stool around a partial obstruction. As in meconium ileus, bubbly, granular material can be detected by radiograph in the region of the obstruction, and regions of stool retention may serve as lead points for intussusception. Some patients experience rectal prolapse secondary to difficulty passing stool and from increased intra-abdominal pressure from coughing.

Symptomatic liver disease is an uncommon manifestation of CF but leads to death in a small minority of the patient population. The characteristic pathologic findings are focal biliary cirrhosis with edema, chronic inflammatory cell infiltration, and bile duct proliferation with patchy accumulation of eosinophilic material in the intrahepatic ducts. The localization of CFTR to the apical membrane of the intrahepatic bile duct cells suggests that a reduction in CFTR activity in CF may result in dehydration and increased viscosity of the bile, which may be a key factor in the pathophysiologic features of the hepatic disease. Prolonged jaundice can occur in neonates, and some patients may develop fatty infiltration of the liver; but the characteristic liver lesion in CF is focal or multilobular cirrhosis. Hepatomegaly is variably detected on examination, and the secondary development of splenomegaly suggests the possibility of portal hypertension. Other

**Figure 239-2** Cross-sectional analysis of the CF Foundation Patient Registry Annual Data Report showing the association between body mass index (BMI) percentile and pulmonary function. Note the decreased lung function associated with BMI below the 50th percentile. (Reprinted with permission from Cystic Fibrosis Foundation Patient Registry, 2011 Annual Data Report. Bethesda, MD: Cystic Fibrosis Foundation; 2012.)

features of portal hypertension such as variceal bleeding have been reported in CF but are relatively rare.

### Body Fluids

The identification of increased electrolytes in the sweat of people with CF, described decades before the identification of the CF gene, provided important insights into the pathophysiologic mechanism of the disease and led to the development of the diagnostic sweat test. The loss of body electrolytes caused by sweating in patients with CF can cause metabolic alkalosis either acutely or chronically. Acute illness, vomiting, and thermal stress may be contributing factors. Children may initially present with failure to thrive, irritability, and vomiting. Salt crystals are sometimes seen caked on the skin. Laboratory tests reveal increased serum pH and bicarbonate levels, as well as decreased serum levels of sodium, chloride, and potassium. The increased consumption of salty foods in older children and the addition of salt to the formula for infants are usually adequate to prevent salt loss syndrome.

### Pancreas

Patients with CF are also prone to the development of diabetes, particularly in their late teens and adulthood. This important complication has been associated with increased morbidity and mortality in patients with CF. Cystic fibrosis-related diabetes (CFRD) results primarily from a relative insulin deficiency caused by gradual destruction of the islet cells in the pancreas, but an element of insulin resistance has also been reported. Patients with CFRD rarely develop diabetic ketoacidosis, but they are at risk for other complications of diabetes such as retinopathy, renal dysfunction, and neuropathy. Patients may have the classic symptoms of diabetes such as polyuria and polydipsia and weight loss, but many have minimal symptoms. CFRD should be considered as a possible cause for poor growth, delayed puberty, increased frequency

of pulmonary exacerbations, or unexplained decline in pulmonary function. Patients who do not have CFRD should have annual screening with a 2-hour glucose tolerance test beginning at 10 years of age. Hospitalized patients, particularly those receiving supplemental feedings via gastrostomy tube, should have frequent blood sugar measurements because altered glucose metabolism may be present only during times of acute illness or stress. Patients with CFRD should *not* be placed on a diabetic diet because a significant reduction in caloric intake might result, which can compromise the patient's overall nutritional status. Instead, patients are taught how to distribute carbohydrates more equally throughout the day and to replace sweetened beverages with diet drinks. Insulin is the therapy of choice. Patients with CFRD should have hemoglobin A1C levels measured quarterly to assess adequacy of glucose control.

### Skeletal Complications

Osteopenia and osteoporosis are relatively common in adolescents and adults with CF for several reasons, including failure to thrive, delayed pubertal development, liver disease, physical inactivity, and malabsorption of calcium, magnesium, and vitamins D and K. Steroid use may further exacerbate the problems. Patients with decreased bone mineral density are predisposed to atraumatic fractures, especially of the spine and ribs. Patients may also experience transient arthritis that may be monoarticular, pauciarticular, or polyarticular. The knees, ankles, wrists, and proximal interphalangeal joints of the hands are the most often affected.

### Puberty

Pubertal development is often delayed in both boys and girls with CF. Poor nutritional status and a decrease in glucose tolerance, accompanied by a delay in the rise in sex hormone levels, result in delayed or

blunted pubertal development. Female infants with CF demonstrate excessive cytoplasmic and extracellular mucus, which can continue into childhood; the thickened cervical secretions may reduce fertility. Girls with CF may have abnormal menstrual cycles, as well as primary and secondary amenorrhea. Nevertheless, increasing numbers of successful pregnancies are occurring as the CF population ages. Boys with CF may have reduced testicular and epididymal size and reduced testosterone levels. In the majority of boys, bilateral absence of the vas deferens occurs secondary to obstruction and subsequent resorption of the structure, resulting in infertility. However, a variety of assisted reproductive technologies have recently been developed and used to successfully treat infertility in men with CF.

## DIFFERENTIAL DIAGNOSIS

The institution of newborn screening for CF has significantly altered the clinical picture of the newly diagnosed child. In 2013, 62% of all new diagnoses arose from a positive newborn screen. These infants are generally asymptomatic from the pulmonary standpoint. They may exhibit signs of malabsorption and weight gain issues depending on their pancreatic status. There are still patients, both pediatric and adult, however, who are diagnosed each year based on their clinical picture. For these patients, they most commonly exhibit respiratory symptoms such as recurrent pulmonary infections (18% of patients at presentation), failure to thrive or malnutrition (5%), steatorrhea or abnormal stools (6%), meconium ileus or intestinal obstruction (10%), or a family history of CF (9%). Vitamin deficiency (specifically deficiencies in the fat-soluble vitamins A, D, E, and K) may be seen. Other manifestations of CF that may trigger initial patient encounters include salt loss syndrome, nasal polyps, hepatobiliary disease, and impaired fertility.

For patients not diagnosed in the newborn period, the common pulmonary symptoms at presentation include a recurrent cough that is productive of purulent sputum, difficult-to-control wheezing, nasal polyps, recurrent otitis media, sinusitis, and pneumonia. The differential diagnosis includes asthma, environmental allergies, immunodeficiency syndromes, ciliary agenesis or dyskinesia,  $\alpha$ -1-antitrypsin deficiency, and foreign body aspiration.

From the gastrointestinal standpoint, infants with CF may present with steatorrhea, abdominal bloating with feedings, and difficulty gaining weight. Older children most commonly present with failure to thrive (see Chapter 149, Failure to Thrive: Pediatric Undernutrition) or steatorrhea (see Chapter 138, Diarrhea and Steatorrhea).

## EVALUATION

### Relevant History

In the majority of cases, no known family history of CF is found.

Infants diagnosed based on newborn screening are generally asymptomatic with the possible exception of steatorrhea, or frequent foul-smelling stools. For older children diagnosed based on symptoms, cough is the

most common presentation. The cough is often dry at first but becomes progressively productive of purulent sputum. Over-the-counter therapies are generally ineffective, and antibiotic treatment can produce only transient, partial improvement in the cough, which recurs with the cessation of therapy. The cough is present both day and night and may be exacerbated by physical activity and, in infants, by crying. Recurrent wheezing may also be present. Some children with CF also have asthma. Parents often report that their child has had recurrent pneumonia, sinusitis, bronchitis, and otitis media, necessitating repeated courses of antibiotics. Pneumonia and atelectasis may have occurred repeatedly in the same area of the lung. A history of nasal polyps without a concomitant history of nasal allergies is highly suggestive of CF. Finally, parents may have noted changes to the child's nail beds consistent with clubbing.

From the gastrointestinal standpoint, infants with CF are often described as voracious feeders despite having poor weight gain. The infants' stools are frequent, bulky, loose, foul smelling, and voluminous enough that parents will often complain that they overflow the diaper. Grease may be seen in the stool, absorbed in the diaper, or, in the case of older children, in the toilet bowl. Abdominal cramping and bloating after eating are common complaints. Foul-smelling flatulence may be described. Any neonate born with meconium ileus or with delayed passage of meconium and any infant or child with rectal prolapse should be tested for CF.

## Physical Examination

### Vital Signs

Respiratory rates and heart rates should be monitored relative to age-appropriate normal values. Fever and exacerbation or progression of the underlying lung disease may elevate both values. Oxygen saturation should be assessed at each visit. The use of overnight pulse oximetry or polysomnography should be considered to evaluate for nocturnal hypoxemia and hypercarbia in patients with more advanced disease.

### Growth Parameters

At all ages, particular attention should be paid to growth parameters, including weight, height, head circumference, and weight for length in children younger than 2 years and weight, height, and body mass index (BMI) in children older than 2 years. The child's height percentile should be compared with that predicted from the parental height. Concern should arise whenever a child fails to gain weight, loses weight, or crosses percentiles for height or weight.

### Head and Neck

Otoscopic examination should be performed at all visits to assess for otitis media. If a child has recurrent otitis media or is exposed to frequent doses of aminoglycosides, then audiometry should periodically be performed. The nasal mucosa should be inspected for discharge, swelling of the tissue, or polypoid tissue. Palpation of the sinuses should be performed.

Examination of the oropharynx should include assessment of the tonsils and the posterior pharynx because children with CF have similar risk for the development of adenotonsillar hypertrophy as children without CF. The posterior pharynx should be checked for exudates emanating from the nasopharynx.

### **Chest and Lungs**

Coughing frequency and the productivity of the cough should be assessed. The child's ability to communicate without coughing and becoming dyspneic, and without accessory muscle use is indicative of the status of the lung disease. Auscultation of the lungs may reveal clear breath sounds. With exacerbation of the underlying lung disease, wheezing, rhonchi, or crackles may be heard. As the patient's pulmonary status worsens, these findings may not change with antibiotic therapy; any clearing that does occur may be short lived. As the lung disease progresses, breath sounds may become globally decreased, and tubular breath sounds may be heard in areas of severe tissue destruction or bronchiectasis and fibrosis. Unilaterally decreased breath sounds, particularly in association with an acute onset of dyspnea, should raise concern about the development of a pneumothorax. With progression of the obstructive component of CF lung disease, there is increasing hyperinflation of the lungs, and the chest may take on a barrel shape with an increased anterior-posterior diameter. Progression of the fibrotic component of the lung disease results in the development of tachypnea and decreased vital capacity.

### **Heart**

With the progression of the lung disease and development of cor pulmonale, fixed splitting of the first and second heart sounds with increased loudness of the second heart sound may be heard.

### **Abdomen**

Infants may present with protuberant abdomen. Distention of the abdomen with pain on palpation may be noted in children with acute intestinal obstructions. The frequency and distribution of bowel sounds should be assessed by auscultation. Palpation should be performed to assess for retention of stool (most commonly in the right lower quadrant), tenderness, hepatomegaly, and splenomegaly.

### **Genitourinary Tract**

Tanner staging should be performed either by direct inspection or by having the child indicate developmental status from a series of pictures. Girls should be questioned about the onset of menstruation, the regularity of their cycles, and associated symptoms. All sexually active girls should undergo annual pelvic examinations.

### **Extremities**

Joints should be examined for swelling that may be caused by CF-related arthropathy. The digits and nail beds should be examined for clubbing and cyanosis. Edema may arise from hypoproteinemia, especially in newly diagnosed malnourished infants and in patients with end-stage lung disease and cor pulmonale.

## **Laboratory Testing**

### **Diagnostic Testing: Sweat Testing and Genotype Analysis**

The diagnosis of CF requires either 2 positive sweat tests or genotype analysis revealing 2 *CFTR* mutations known to cause CF plus 1 of the following:

- Chronic sinopulmonary disease
- Gastrointestinal or nutritional abnormalities
- Obstructive azoospermia in boys
- Salt loss syndrome
- CF in a first-degree relative

The pilocarpine iontophoresis technique of Gibson and Cooke is the gold standard for the diagnosis of CF. Pilocarpine stimulates the secretion of sweat. The volume of sweat and concentration of chloride secreted are then measured. Sweat testing should be performed in accordance with the Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards) guidelines. Normative sweat chloride values are age dependent. Normal sweat chloride values in infants up to 6 months of age are less than or equal to 29 mEq/L. Levels between 30 and 59 mEq/L are borderline, and repeat sweat testing/genetic testing should be performed. Values greater than or equal to 60 mEq/L are indicative of CF. Normal chloride values in individuals older than 6 months of age are less than 40 mEq/L. Values between 40 and 60 mEq/L are considered borderline, and repeat sweat testing or genetic testing is required to make a definitive diagnosis. For some borderline cases, referral to specialized centers for an assessment of *CFTR* function by measuring nasal potential difference may be needed to confirm or rule out the diagnosis of CF. For example, in the case of a borderline sweat test result with identification of only 1 *CFTR* mutation, abnormal results on 2 nasal potential difference tests are indicative of a CF diagnosis. Chloride values greater than 60 mEq/L are considered diagnostic of CF, but many possible causes of false-positive sweat tests exist, including laboratory error, untreated adrenal insufficiency, autonomic dysfunction, ectodermal dysplasia, glucose-6-phosphate deficiency, hypothyroidism, malnutrition, mucopolysaccharidosis, glycogen storage disease (type 1), fucosidosis, hereditary nephrogenic diabetes insipidus, Mauriac syndrome, pseudohypoaldosteronism, or familial cholestasis. A repeat confirmatory sweat test should be performed together with genetic mutation analysis. In asymptomatic newborns, sweat testing triggered by a positive CF newborn screening report should be performed when the infant is at least 2 weeks of age and weighs more than 2 kg. In symptomatic newborns, sweat testing may be performed as early as 48 hours of age, but the probability of inconclusive results is greater at this age. False-negative values can result from edema, malnutrition, and laboratory error. Several *CFTR* mutations that cause CF can also result in a false-negative sweat test.

In cases in which genetic testing is done as part of a newborn screen algorithm or when genetic testing alone is performed, the presence of 2 mutations known to cause CF is diagnostic; however, sweat testing is still recommended to confirm *CFTR* protein dysfunction. In cases in which genetic testing is done to resolve a

borderline sweat test or following an abnormal sweat test, the presence of 2 mutations known to cause CF is confirmatory of the diagnosis. DNA from blood or buccal swabs can be used for genetic testing. With the advent of mutation-specific therapies to treat patients with CF, it is recommended that all patients undergo genetic testing to identify both CF-causing mutations.

### Newborn Screening

Newborn screening for CF has been universally adopted in the United States. An expert panel convened by the Centers for Disease Control and Prevention (CDC) and the Cystic Fibrosis Foundation in November 2003 reviewed the data on the risks and benefits of newborn screening with the recommendation that “on the basis of evidence of moderate benefits and low risk for harm, CDC believes that newborn screening for CF is justified.” Evidence exists to support the efficacy of newborn screening in the areas of improved nutritional status, cognitive development, economic benefit, and improved survival. The impact of newborn screening on pulmonary status is variable. The benefit of improved height and weight on pulmonary status is well known and believed to outweigh the variability in data concerning pulmonary outcomes for newborn screening.

Newborn screening for CF is typically a 2-tier test. The first tier involves measuring serum immunoreactive trypsinogen (IRT) levels. IRT values are elevated in newborns with CF, but false-negative results may occur, particularly in infants with meconium ileus. All infants with meconium ileus should undergo sweat testing or genetic analysis. The second tier of testing varies between states and may use either repeat IRT measurement or limited genetic mutation analysis. Sweat testing is performed to confirm results of newborn screening. In cases in which the child has signs and symptoms consistent with CF, sweat testing or genetic analysis should be performed regardless of newborn screening results.

### Recommended Monitoring of Patients With an Established Diagnosis of Cystic Fibrosis

The Cystic Fibrosis Foundation has developed guidelines for the management of infants with CF that are applicable for those infants diagnosed by newborn screening as well as those whose diagnosis was initially suggested through symptoms or clinical presentation such as meconium ileus. Infants should be seen monthly for at least the first year of life and then every 2 to 3 months for the second year. After 2 years, it is recommended that all patients with CF should be evaluated in an accredited CF center at least quarterly. The Cystic Fibrosis Foundation recommends that infants with CF should have a complete blood count with differential, fat-soluble vitamin levels (retinol,  $\alpha$ -tocopherol, 25-hydroxyvitamin D), albumin and pre-albumin, prothrombin time, and measurement of liver enzymes performed initially between 1 and 3 months of age. After that, patients should have these studies repeated annually. Pancreatic functional status should be assessed in all infants diagnosed by newborn screening using fecal elastase measurement within the first month of life. Patients 10 years and older should be screened for CF-related diabetes mellitus on an annual basis (Figure 239-3). Patients who are on chronic inhaled aminoglycoside therapy or who receive frequent courses of intravenous aminoglycosides should have at least annual measurement of renal function. All patients should receive a complete physical examination, including hearing and vision screening annually, which is particularly relevant for patients receiving multiple courses of aminoglycosides because of their potential ototoxicity.

### Microbiologic Assessment

Cultures to assess lower respiratory tract flora should be obtained initially 1 week after diagnosis or at 1 month of age and then at 3, 6, and 12 months of age. After 1 year of age, clinically stable patients should undergo culture of the respiratory tract at least quarterly and

#### Healthy Outpatients

- OGTT of choice
- Diagnosis based on
  1. FPG  $\geq 126$  mg/dL
  2. 2-hr OGTT glucose  $\geq 200$  mg/dL
  3. A1C  $\geq 6.5\%$
  4. Random glucose  $> 200$  mg/dL plus polyuria, polydipsia
- All but #4 should be repeated

#### Acute Illness, Systemic Steroids

- Diagnosis based on hyperglycemia that persists for  $> 48$  hr
- Hyperglycemia is defined as
  1. FPG  $\geq 126$  mg/dL
  2. 2-hr postprandial glucose  $\geq 200$  mg/dL
- If measured by SMBG, should be confirmed by laboratory measurement

#### Continuous Drip Feedings

Diagnosis based on mid- or immediate postfeeding glucose  $\geq 200$  mg/dL  
Should be confirmed on 2 separate nights  
If measured by SMBG, should be confirmed by laboratory measurement

**Figure 239-3** Screening algorithm for diabetes. All children 10 years or older should undergo an oral glucose tolerance test (OGTT) annually. FPG, fasting plasma glucose; SMBG, self-monitoring blood glucose. (Modified with permission from Moran A, Brunzell C, Cohen RC et al. *Clinical Care Guidelines for Cystic Fibrosis-Related Diabetes: A position statement of the American Diabetes Association and a clinical practice guideline of the Cystic Fibrosis Foundation, endorsed by the Pediatric Endocrine Society*. Diabetes Care. 2010;33:2697–2708.)

whenever there is any change in clinical status. Due to the relatively high prevalence of NTM infections in patients with CF, annual screening with mycobacterial cultures is recommended for those patients who can expectorate sputum. An expectorated sputum sample is the usual way to obtain this culture. In infants and young children who are unable to expectorate, a throat swab or cough swab is often obtained, but it is not necessarily predictive of lower airway pathogens. In young children, *S aureus* and *H influenzae* are the most common organisms. With advancing age, *P aeruginosa* becomes the predominant pathogen. Other pathogens such as *Burkholderia cepacia* complex and *Stenotrophomonas maltophilia* can also infect the CF lungs (Figure 239-4). The prevalence of methicillin-resistant *S aureus* has been increasing over the past decade. Specialized media are recommended to ensure isolation of common CF pathogens. *P aeruginosa* is best detected using MacConkey agar, *S aureus* on mannitol salt agar or Columbia or colistin-nalidixic acid, *H influenzae* on horse blood or chocolate agar, and *B cepacia* complex using *B cepacia* selective agar, oxidation-fermentation polymyxin bacitracin lactose agar, or *Pseudomonas cepacia* agar. After a pathogen has been isolated, antimicrobial susceptibility testing should be determined using an agar-based diffusion assay such as E-tests (antibiotic-impregnated strips) or antibiotic discs rather than automated commercial systems, which have been shown to be inaccurate in these circumstances. Organisms in the *B cepacia* complex and other unidentified gram-negative rods should be sent to a reference laboratory, such as the Cystic Fibrosis Foundation-sponsored *B cepacia* laboratory at the University of Michigan, for further evaluation.

### Spirometry

Spirometry should be performed every 3 to 6 months and as needed based on the patient's pulmonary status. Although most children younger than 6 years are unable to perform the test reliably, new approaches are being developed that may allow the extension of this test to younger patients, and infant pulmonary function testing is available at many CF centers. Spirometry is best performed with the supervision of a certified respiratory therapist who is trained to work with children because it may be difficult to get a reliable, reproducible effort, especially when the child is first learning to perform the test.

The changes seen in pulmonary function are obstructive in nature secondary to plugging of the small airways with thick secretions. The severity of pulmonary disease as defined in the *CF Foundation Patient Registry Annual Data Report* is categorized based on the percentage predicted forced expiratory volume in 1 second (FEV<sub>1</sub>). Normal lung function is defined as an FEV<sub>1</sub> more than 90%, mild lung disease 70% to 89%, moderate 40% to 69%, and severe less than 40%. Less than 20% of children reported in the *CF Foundation Patient Registry Annual Data Report* have moderate to severe lung disease (Figure 239-5). One measure of the health of the small airways is FEF<sub>25%-75%</sub> (forced expiratory flow between 25% and 75% of vital capacity), the average amount of air expelled over the middle half of all the air expelled during spirometry. Researchers have suggested that changes may be seen in a forced expiratory flow of 25% to 75% before FEV<sub>1</sub>, and therefore clinicians should consider this value, particularly in younger children.

**Figure 239-4** Prevalence of pulmonary pathogens based on the age of the patient. MDR-PA, multidrug-resistant *Pseudomonas aeruginosa*; MRSA, methicillin-resistant *Staphylococcus aureus*. <sup>a</sup>*S aureus* includes people with MRSA. <sup>b</sup>*P aeruginosa* includes people with MDR-PA. ### Imaging

A chest radiograph should be performed on infants initially between 2 and 6 months of age, at 1 and 2 years of age, and then every 2 to 4 years in patients who are clinically stable, annually in patients with declining pulmonary function, and as clinically indicated at times of pulmonary exacerbation in all patients. Bronchial wall thickening, together with hyperinflation caused by small airway obstruction, is the first change noted. Bronchiectasis develops with time. Acute or chronic infiltrates may be noted depending on the clinical status of the patient. The progression of radiographic changes varies between patients and may be more sensitive than changes in pulmonary function tests. Pulmonary function may be relatively well maintained at the same time that radiographic changes may be fairly advanced.

Chest CT scans also show that structural changes in the lung can often be detected before symptoms are present. Although some enthusiasm has existed for periodic chest CT scans, concerns about the radiation exposure have limited adoption of this approach. No current formal recommendations have been made for routine performance of CT scanning in patients with CF.

Patients 8 years or older with CF who are malnourished, have severe pulmonary disease, are on chronic glucocorticoid therapy, have delayed puberty, or have low levels of 25-hydroxyvitamin D are at increased risk for bone disease. Lateral chest radiographs of these patients should be examined for fractures at

least annually. Children with these risk factors who are at least 8 years of age should undergo a dual radiograph absorptiometric scan to measure bone density. All children with CF should have bone densitometry performed by their 18th birthday. An abdominal ultrasound should be performed if a change is noted in liver function tests or if hepatomegaly or splenomegaly is detected.

### MANAGEMENT

All children diagnosed with CF and those who have clinical stigmata of CF but equivocal diagnostic test results should be referred to a local CF care center for evaluation. At the center, children are evaluated by a pediatrician (most often a pediatric pulmonologist), nurse, respiratory therapist, dietitian, and social worker who are highly experienced in the management of CF. These individuals are able to provide counseling and support to families of newly diagnosed children, as well as education about the disease. Pulmonary and gastrointestinal therapies can be initiated. Infants should be seen monthly for the first year of life and then every 2 to 3 months during the second year to facilitate ongoing education of the family about CF, to assure adequate growth and nutrition for the child, and to adjust or initiate therapies as needed. Children should be seen at least quarterly in the CF care center where the adequacy of their therapies, as well as their growth, nutrition, and pulmonary function, can be assessed and therapies adjusted accordingly. The CF social worker is an invaluable resource for families and can help them deal with the psychological and financial aspects of raising a child with CF. The team will work with the child over the years to help them develop into an adult capable of managing the disease independently. CF centers are also able to make available to patients clinical trials of the newest cutting-edge therapies. The CF center should not be considered, however, as a replacement for the primary care pediatrician. The child absolutely must continue to receive routine well-child care. CF centers generally have physicians available at all times to consult on medical management issues relating to CF. A list of accredited CF care centers in the United States can be accessed via the Cystic Fibrosis Foundation Web site ([www.cff.org](http://www.cff.org)).

### Pulmonary Therapy

The Cystic Fibrosis Foundation has developed a series of guidelines related to airway clearance, chronic medications, management of pulmonary exacerbations, and management of pulmonary complications such as hemoptysis and pneumothorax. From the moment a child is diagnosed with CF, the family should be counseled to minimize environmental tobacco smoke exposure. Children, especially adolescents, should be educated about the detrimental effects of tobacco smoke and illegal inhalants on their lungs. Infants and children with CF should receive all routine childhood vaccinations including annual vaccination for influenza. Nasal spray vaccination for influenza should not be used. Currently, the American Academy of Pediatrics does not recommend palivizumab prophylaxis for all infants with cystic fibrosis. It should be

considered for infants with evidence of chronic lung disease and/or nutritional compromise. The decision to pursue authorization for palivizumab prophylaxis should be based on risk/benefit and cost discussions between the provider and the family. Annual influenza vaccination is recommended for children with CF older than 6 months and their families.

The cornerstone of pulmonary therapy for children and adults with CF is chest physiotherapy (CPT). Patients are prescribed a daily regimen of CPT to help them mobilize and expectorate the thick, tenacious secretions in their airways. The frequency of therapy is generally increased during times of acute exacerbations. Numerous airway clearance modalities are available for CPT, including manual percussion with postural drainage, autogenic drainage, or a vest that inflates and vibrates the chest at different frequencies. Several different handheld devices are designed to shear the mucus off the airways and provide back-pressure to stent the airways open such that secretions may be expelled. Each modality has specific advantages, but no single modality is superior. Because CPT is a time-consuming process, the choice of therapy should be based on the method that is the most effective for that patient and that fits best into the family's lifestyle to optimize adherence. Physical activity and regular exercise should be recommended as an integral part of the regimen.

Bronchodilators are often given before CPT to maximally dilate the airways and thus help facilitate clearance of the secretions. Patients with CF have a variable response to  $\beta$ -agonists, and some patients exhibit a transient decline in pulmonary function most likely secondary to collapse of bronchiectatic airways. Patients with CF should be assessed for bronchodilator response by pulmonary function testing and therapy adjusted accordingly. Long-acting  $\beta$ -agonists, however, may be beneficial in some patients with CF and asthma.

The chronic inflammatory process in CF lung disease has led to considerable interest in anti-inflammatory therapies. Alternate-day prednisone therapy has been shown to improve lung function in patients chronically infected with *P aeruginosa*, but an increased incidence of growth restriction, glucose abnormalities, and cataracts has dampened enthusiasm for this therapeutic approach. Inhaled steroids and leukotriene modifiers are attractive alternatives and are widely prescribed. However, because of a lack of evidence of efficacy for CF treatment, their use should be limited to patients with concomitant asthma. In patients with CF who have mild lung disease, high-dose ibuprofen has been shown to decrease the rate of decline in lung function and the need for hospitalization. However, the requirements for a pharmacokinetic study to determine the optimal dose of ibuprofen and concerns about safety have limited penetration of this therapy into clinical practice.

Dornase alpha, a recombinant human deoxyribonuclease, was developed for nebulization into the airways, where it cleaves the viscous DNA released by dying neutrophils as part of the exaggerated inflammatory response characteristic of CF lung disease. Deoxyribonuclease treatment improves the rheologic

properties of the sputum and enables the patient to expectorate the sputum more easily. It is generally administered once a day. A multicenter study of dornase alpha revealed an improvement in lung function and a decrease in the frequency of pulmonary exacerbations with chronic use. This therapy is recommended for children 6 years of age or older unless they have documented intolerance for the drug. Inhaled hypertonic saline is one of the newest therapies in the CF armamentarium. The hypothesis is that inhaling a highly concentrated saline solution (7% saline) increases the osmotic load and stimulates water movement into the airways. The improved hydration of the secretions results in better mucociliary clearance, and patients are better able to clear their secretions. A 48-month trial of 7% saline inhaled twice daily revealed improved pulmonary function, and treated patients had fewer pulmonary exacerbations compared with controls who inhaled 0.9% saline twice daily. Some patients may experience wheezing with the medication, which can be attenuated by pretreatment with a bronchodilator. This therapy is recommended for children 6 years of age or older.

Chronic daily antibiotic therapy to prevent the initial infection or to treat chronic bacterial infection is not well supported by evidence in medical literature. Antibiotic therapy is generally recommended for treating acute exacerbations when the bacterial burden increases and patients develop associated symptoms such as increased cough frequency and sputum production or declining pulmonary function with or without radiographic changes. One of the exceptions to this rule is the chronic use of macrolide antibiotics. Research has shown that 3-times-a-week administration of the macrolide antibiotic azithromycin for older children and adults with CF who are chronically colonized with *P aeruginosa* has a positive impact on lung function, weight, and the frequency of pulmonary exacerbations. As such, this therapy is recommended for children 6 years of age and older with *P aeruginosa* persistently present in their airway cultures. A study of the use of 3-times-a-week administration of azithromycin in older children and adults who were culture negative for *P aeruginosa* for at least 1 year showed a positive impact on weight, frequency of pulmonary exacerbations, and cough frequency. A high-dose preparation of nebulized tobramycin given twice a day on alternating months to patients chronically infected with *P aeruginosa* reduced the need for hospitalization and improved pulmonary function. This therapy is recommended for children 6 years of age and older with *P aeruginosa* persistently cultured from the airways independent of the severity or acuteness of the lung disease. A nebulized form of aztreonam lysine was shown to improve patient-reported respiratory symptoms, FEV<sub>1</sub>, sputum density of *P aeruginosa*, and weight. This therapy has been approved for use in children 6 years of age and older with *P aeruginosa* cultured from the airways.

When patients experience an exacerbation of bronchopneumonia or an apparent viral respiratory illness, antibiotic therapy directed against their most recently cultured pathogen is recommended. If the patient does not have respiratory distress or hypoxemia, then

oral outpatient therapy may be initiated. When patients exhibit an acute worsening of their respiratory status, hypoxemia, or respiratory distress, hospitalization with the administration of intravenous antibiotics and aggressive chest physiotherapy is recommended. *P. aeruginosa* is routinely treated with 2 antipseudomonal antibiotics. The duration of antibiotic therapy depends on the severity of the exacerbation but is generally 10 days or longer based on the response to treatment. Airway clearance therapies should be increased in frequency. Chronic maintenance therapies should be continued during treatment for an acute exacerbation.

Hemoptysis and pneumothorax are both common complications of CF lung disease. Patients with CF may have blood-streaked sputum; however, if the volume of blood expectorated is large ( $>240$  mL), then treatment with bed rest, intravenous antibiotics, and cessation of any medications with anticoagulant properties should be initiated. If the bleeding does not resolve or becomes life threatening, then bronchial artery embolization may be required. Resection of the bleeding segment is the therapeutic option of last resort. Pneumothorax occurs annually in approximately 1% of patients with CF. Patients with respiratory distress or with a large pneumothorax ( $>3$  cm between the apex and cupola) should be treated with a chest tube. Pleurodesis is recommended for patients with recurrent large pneumothoraces.

As the lung disease progresses, intervals of stability between exacerbations may become shorter. Patients may require supplemental oxygen therapy because of progressive hypoxemia. Noninvasive ventilation may be instituted when evidence exists of carbon dioxide retention or sleep-disordered breathing.

Lung transplantation is a final therapeutic option for the treatment of progressive, severe lung disease. It is an inherently risky procedure, with a 5-year post-transplantation survival of approximately 50% to 60%. Referral for lung transplantation should be made when other therapeutic options are exhausted. Survival models have been developed that facilitate the calculation of a patient's predicted survival without a transplant to help in the selection of patients most likely to gain a survival advantage from the procedure. Patients are informed of the advantages, risks, and potential complications of undergoing the procedure. They are made aware that the complicated medical regimen that they follow to treat their CF-related lung disease is replaced by a transplant medical regimen that is often equally as complicated. Active tuberculosis, human immunodeficiency virus infection, and hepatitis B are contraindications to lung transplantation. Additionally, patients with significant psychosocial dysfunction that would preclude adherence to the post-transplantation medical regimen are not good surgical candidates for transplantation. Ivacaftor is a drug that acts to optimize the function of the CFTR channel in patients with G551D and other gating mutations by helping to increase the time that the CFTR channel remains open at the cell surface. Clinical trials have shown that patients with the G551D mutation who take the drug demonstrate significant improvement in lung function, risk for pulmonary

exacerbations, patient-reported respiratory symptoms, and sweat chloride concentration. The drug has been approved for the treatment of G551D and other gating mutations. Research is ongoing for the development of other drugs that potentiate CFTR function and correct the abasic genetic defect with the goal that CF patients with all the different genetic mutations will ultimately be able to be treated. Clinical trials have shown that patients with the G551D mutation who took the drug demonstrated significant improvement in lung function, risk for pulmonary exacerbation, patient-reported respiratory symptoms, weight, and sweat chloride concentration. This drug has recently received US Food and Drug Administration approval for treatment of patients with the G551D mutation. Research is ongoing for the development of other drugs that potentiate CFTR function and correct the basic genetic defect with the goal that CF patients with all the different genetic mutations will ultimately be able to be treated.

### Gastrointestinal Therapy

Nutritional therapy is a cornerstone of good CF therapy. Infants and children with CF who have PI should receive at least 120% to 130% of the recommended daily allowance of age-appropriate calories. Fat intake should make up 35% to 40% of the daily required calories compared with less than 30% in people without CF. For infants with CF, nutritional status, adequacy of weight gain, and caloric intake should be assessed at each visit. Human milk is the preferred initial type of feeding, but if this is not possible, standard infant formulas should be used. Increased calorie concentrations may be needed if there is inadequate weight gain. Infants less than 2 years of age should receive  $\frac{1}{8}$  teaspoon of table salt per day starting at diagnosis, and this should be increased to  $\frac{1}{4}$  teaspoon beginning at 6 months of age. Children older than 2 years should be evaluated at least annually by a dietitian who is knowledgeable about CF. Caloric requirements are higher when acute illness or exacerbation of the pulmonary disease is present and when catch-up growth is needed. Lack of appetite caused by intercurrent illness and an inability to consume the increased number of calories needed to sustain normal growth, to make up for lost weight, or to achieve catch-up growth is a frequent nutritional problem faced by both adults and children with CF. Modifications are initially made to increase the caloric density of the child's regular diet. High-calorie, high-fat supplements in the form of shakes and formulas are also recommended. If the child cannot orally consume the needed daily requirement of calories, then supplementation via nasogastric or gastrostomy tube is recommended.

Pancreatic enzyme supplements are given with each fat-containing meal or snack. The recommended dose for infants is 2,000 to 5,000 units of lipase per 120 mL of formula or per breastfeeding. The dose may be adjusted to no greater than 2,500 lipase units per kilogram per feeding, with a maximum daily dose of 10,000 lipase units per kilogram. Low-dose, enteric-coated enzyme preparations can be administered to infants with a small amount of apple sauce or other nonalkaline food. Brand-name enteric-coated enzymes

**Table 239-1** Dosages for Vitamin Supplementation

	VITAMIN A (IU)	VITAMIN E (IU)	VITAMIN D (IU)	VITAMIN K (MG)
0–12 months	1,500	40–50	400–500	≥0.3 mg
1–3 years	5,000	80–150	800–1,000	≥0.3 mg
4–8 years	5,000–10,000	100–200	800–1,000	≥0.3 mg
>8 years	10,000	200–400	800–1,000 (upper limit increases to 2,000 at >10 years)	≥0.3 mg

Derived from Tangpricha V, Kelly A, Stephenson A, et al. An update on the screening, diagnosis, management, and treatment of vitamin D deficiency in individuals with cystic fibrosis: evidence-based recommendations from the Cystic Fibrosis Foundation. *J Clin Endocrinol Metab.* 2012; 97(4):1082–1093; modified from Cystic Fibrosis Foundation. Pediatric nutrition for patients with cystic fibrosis. In: *Consensus Conferences: Concepts in CF Care, 2001*. March 28–29, 2001. Reprinted by permission of the Cystic Fibrosis Foundation.

should be used exclusively. Infants are at risk for developing ulceration of the oral mucosa if the enzymes are not completely cleared from the oral cavity. Enteric coating protects the enzymes from being destroyed by stomach acids. Generic preparations should be avoided because of a lack of standardization of the enzyme dose. Enzyme dosing is initially determined based on the patient's weight and subsequently adjusted based on clinical symptoms of continued malabsorption (frequency and consistency of stools, perceived greasiness of stools, and abdominal cramping). Enzyme therapy for children younger than 4 years should be initiated at a dose of 1,000 units of lipase per kilogram per meal; therapy for children 4 years or older should be initiated at a dose of 500 units of lipase per kilogram per meal. Doses should generally be kept to less than 2,500 units of lipase per kilogram per meal or less than 10,000 units of lipase per gram-fat per day to reduce the risk for developing fibrosing colonopathy.

Children with CF should receive a standard, age-appropriate dose of non-fat-soluble multivitamins. Children with pancreatic insufficiency should also receive supplements of vitamins A, D, E, and K (Table 239-1). Vitamin K is supplemented at higher levels in patients with liver disease and abnormalities in clotting or who are on prolonged antibiotic therapy. Special high-dose preparations of these vitamins are available for patients with CF.

Acid blockers should be used as needed to treat gastroesophageal reflux, which is common in patients with CF. In addition, acid suppression may be beneficial for optimization of pancreatic enzyme function.

Distal intestinal obstruction syndrome is a common complication of CF, and patients with vomiting, crampy abdominal pain, and decreased stool output should be evaluated for intestinal obstruction by imaging. If DIOS is diagnosed, then oral intake should be withheld, and intravenous fluids or total parenteral nutrition should be initiated. The obstruction may be relieved with the performance of a gastrografin enema or oral or nasogastric administration of osmotic laxatives (polyethylene glycol). If this therapy does not result in relief of the blockage, then surgical intervention may be needed. Other diagnostic considerations for these symptoms include appendicitis, pancreatitis, cholecystitis, intussusception, and *Clostridium difficile* colitis.

Elevated liver enzymes and abnormal liver function test results or the detection of hepatomegaly or splenomegaly (or both) during examination should raise concern about the possible development of cirrhosis. An abdominal ultrasound should be ordered. Ursodeoxycholic acid has been shown to benefit patients with cholestatic diseases such as primary biliary cirrhosis and is often administered in patients with CF who have hepatobiliary disease in an effort to improve bile flow and to limit further liver damage. Liver transplantation is a therapeutic option when end-stage liver disease develops.

### CFTR Monitors

Recent advances have been made in the development of a new drug, ivacaftor, that acts to optimize the functioning of the CFTR channel in patients with the G551D mutation by helping to increase the time that the CFTR channel remains open at the cell surface. Clinical trials have shown that patients with the G551D mutation who took the drug demonstrated significant improvement in lung function, risk for pulmonary exacerbation, patient-reported respiratory symptoms, weight, and sweat chloride concentration. This drug has recently received US Food and Drug Administration approval for treatment of patients with the G551D mutation. Research is ongoing for the development of other drugs that potentiate CFTR function and correct the basic genetic defect with the goal that CF patients with all the different genetic mutations will ultimately be able to be treated.

### SUMMARY

The improved survival for patients with CF over the recent decades is likely to continue as more is learned about the pathobiologic characteristics of the disease. The therapeutic options for patients with CF have significantly increased over the past decade. The challenge to the CF practitioner is in choosing the best, most appropriate combination of therapies for the individual patient aimed at maintaining optimal health status. Consultation with the regional CF care center and physicians who are experienced with the nuances of CF care is strongly recommended. More specific therapies aimed at the basic defect in CF are now being developed, with the ultimate goal of delivering a therapy to infants with CF that will provide them with long and healthy lives.

We gratefully acknowledge Dr Terry B. White for her assistance in the final editing and referencing of the chapter.

### WHEN TO REFER

- All children with CF should be referred to a local CF center for ongoing care.

### WHEN TO ADMIT

- The patient who has pulmonary exacerbations characterized by increased cough, sputum production, and a decline in pulmonary function should be admitted. Associated symptoms may include fever, wheezing, dyspnea, malaise, and weight loss. Acute changes in the chest radiograph may or may not be seen. If the patient has normal oxygen saturation on room air, then efforts are made to treat the patient initially with increased pulmonary toilet and oral antibiotics based on the microbiologic characteristics of the most recent sputum culture.
- The patient should be admitted for intravenous antibiotic therapy if response to oral antibiotic therapy is inadequate.
- If the patient is hypoxemic or has major hemoptysis, then the patient should be admitted to the hospital for further management. Hemoptysis of more than 240 mL in 24 hours or more than 100 mL per day over 3 to 7 days is defined as major hemoptysis and should lead to admission. Patients with respiratory distress or with a large pneumothorax ( $>3$  cm between apex and cupola) should be admitted. A patient with a small pneumothorax, who is otherwise clinically stable, may be closely observed as an outpatient depending on the reliability of the patient and family and their ease of access to health care.

## Chapter 240 DENTAL PROBLEMS

Martha Ann Keels, DDS, PhD; Melinda B. Clark, MD

### BACKGROUND

Oral health is a vital component of overall health, and understanding of the oral-systemic disease connection is increasing. This chapter provides pediatricians and other health care professionals the tools to evaluate, triage, and educate families on common conditions of the oral cavity. Pediatricians are responsible for addressing children's health care needs, including oral health, and arranging care with other qualified professionals as needed. This translates into the ability to diagnose, manage, and triage common oral pathology, appropriately reassure or refer, and provide anticipatory guidance to families regarding dental development, teething, oral hygiene, dietary practices, and caries prevention.

### CONGENITAL ORAL FINDINGS

#### Neonatal Oral Findings

Inclusion cysts are small, white or translucent papules or cysts that develop in utero. These congenital findings are seen in 75% of newborns and resolve spontaneously by 3 months of age. Because inclusion cysts are asymptomatic, there is no need for further evaluation or management other than reassurance. Three types of inclusion cysts can be found in newborns.

1. Epstein's pearls are the most common congenital inclusion cysts, occurring in 75% to 80% of all neonates. They are found along the midline raphe of the hard palate and represent epithelial remnants of

palatal fusion. These cysts resolve spontaneously with no intervention.

2. Bohn's nodules are heterotopic salivary gland remnants located on the buccal or lingual mucosal surface of the alveolar ridge (not the crest) or on the hard palate, away from the raphe.
3. Dental lamina cysts are heterotopic salivary gland remnants located on the crest of the alveolar ridge.

### Ankyloglossia

Tongue-tie (ankyloglossia) is a physical defect that results in limited tongue movement and occurs in 4% to 10% of children. Ankyloglossia ranges from a bulky, short membrane of connective tissue to an essentially immobile tongue caused by excessive fiber anchoring the tongue to the floor of the mouth. This restricted tongue movement can lead to a variety of problems in infants and children, such as inability to latch with breastfeeding, improper speech development, and compromised oral health. A constricted lingual frenum has been correlated with increased incidence of dental caries resulting from inability to remove food from the teeth. Intervention for ankyloglossia varies from observation to surgical release of the frenum. If feeding, speech development, or oral health are compromised, then referral to a dentist, plastic surgeon, or otolaryngologist is indicated to evaluate the need for surgical release of the frenum. The surgical procedure, termed a frenectomy or a frenotomy, can be completed with either blunt scissors, cautery, or laser.

## CONDITIONS RELATED TO TOOTH EMERGENCE

### Natal or Neonatal Teeth

Tooth eruption can occur before birth (natal teeth) or within the first month of life (neonatal teeth). Central mandibular incisors are the most likely to erupt early, and these are most often the primary dentition, not extra teeth. Incidence of natal teeth is approximately 1:2,000 to 1:3,000 live births. It is most commonly an isolated finding, but can be associated with genetic syndromes such as chondroectodermal dysplasia. Extraction may be considered if the teeth are mobile and present an aspiration risk, interfere with breastfeeding, or lead to Riga-Fede disease (ulceration). Otherwise, only observation is indicated.

### Eruption Cyst/Hematoma

An eruption cyst is a dome-shaped soft-tissue lesion overlying the erupting tooth that presents 1 to 3 weeks prior to tooth eruption. As the tooth breaks through, the fluid mixes with blood to become blue or purplish and is referred to as an eruption hematoma. No treatment is recommended, because the cyst will resolve spontaneously when the tooth erupts completely. Reassurance should be provided.

### Teething

A number of studies have looked at teething and associated symptoms and have determined that increased drooling, biting, chewing, sucking, rubbing of the gums and ears, facial rash, crying, decreased appetite, mild

temperature elevation, and poor sleep are all statistically associated with teething. No single symptom occurred in more than 35% of infants, and no symptom occurred more than 20% more often in teething than in non-teething infants. Potentially serious symptoms such as fever ( $>100.4^{\circ}\text{F}$ ) and diarrhea should not be attributed to teething and may require further evaluation to rule out a bacterial source of infection.

The recommended intervention for teething is the use of cold items as an anesthetic for the gums. Items that can be refrigerated include pacifiers, spoons, wet washcloths, and teething rings. Topical teething gels sold over the counter (OTC) are often used for teething, but carry serious risks such as local reactions, seizures with overdose, and methemoglobinemia. They should not be used in children younger than 2 years of age. If necessary, parents should be instructed on proper dosing of OTC analgesic medications such as acetaminophen or ibuprofen.

### Atypical Emergence or Exfoliation

Tooth eruption or emergence tends to occur in a predictable pattern, although the timing can vary considerably. Mandibular central incisors typically emerge first, between 5 and 10 months of age. Delayed emergence of more than 12 months can be caused by oral space issues, pacifier or digit pressure, infection, hypertrophied gingival tissue, endocrine or genetic disorders, or radiation therapy. Space limitation, including impacted teeth or another tooth blocking eruption, is the most common reason for isolated tooth eruption delay. Endocrine disorders, including hypothyroidism, hypoparathyroidism, and hypopituitarism can result in eruption delays. Among genetic disorders, ectodermal dysplasias, Down syndrome, and cleidocranial dysostosis include a component of abnormal tooth emergence. Failure to erupt teeth by 18 months of age warrants referral to a dentist for evaluation and radiographs. Even if the timing is normal, an atypical pattern of eruption can be the first presenting sign of a systemic condition. For example, Langerhans cell histiocytosis can present with premature eruption of the molars before the incisors.

Permanent dentition begins to emerge around age 6 years, resulting in exfoliation or loss of the primary teeth. Timing of this process is affected by gender, ethnicity, and family history. Girls tend to erupt permanent teeth earlier than boys. Familial delays in tooth eruption have been linked to *PTHR1* gene mutations, and black children tend to erupt permanent teeth earlier than their white or Asian counterparts. Of note, 15% to 20% of people fail to develop all 4 third molars (wisdom teeth). In an American study, agenesis of the third molars was more common in white than in black adolescents (16% vs 6%) and slightly more common in females than in males (19% vs 14%). Localized premature tooth loss is most often caused by tooth trauma and root necrosis or severe dental caries. Premature tooth loss affecting many or all teeth can be associated with Langerhan cell histiocytosis, endocrine disorders (hypophosphatasia or diabetes mellitus), immune disorders (disorders of neutrophil function, cyclic neutropenia), and connective tissue disorders (eg, Ehlers-Danlos syndrome). Emergence of the permanent teeth is the stimulus for

exfoliation of the primary teeth (natural tooth loss). Therefore, endocrine disorders (hypothyroidism, hypopituitarism, rickets) and genetic conditions (ectodermal dysplasia, trisomy 21, and cleidocranial dysostosis) that are associated with delayed emergence of permanent teeth will be characterized by delayed exfoliation of the primary teeth.

## COMMON ORAL CONDITIONS IN CHILDHOOD

### Dental Caries

Dental caries, one of the most common chronic childhood diseases of childhood, is reviewed separately in Chapter 40, Oral Health.

### Oral Ulcers

Oral ulcers are fairly common in children. There are 3 basic types of ulcers.

1. Traumatic ulcers typically result from mechanical or thermal injury and are the most common oral ulcers in children. They are usually seen on the buccal mucosa, tongue, lips, or palate. Eating or drinking very hot foods can burn the mucosa; traumatic ulcers result from objects in the mouth, lip biting or tongue biting, abuse, and self-injurious behavior. Traumatic ulcers typically heal quickly, within days of the inciting event.
2. Infectious ulcers are also very common in childhood. The most common infections causing oral ulcers are herpes simplex virus (HSV primary or recurrent) and coxsackievirus infections (herpangina and hand-foot-mouth disease). These conditions are discussed in more detail in Chapter 266, Herpes Infections, and Chapter 248, Enterovirus and Evolving Infections.
3. Aphthous ulcers are best known as “canker sores” and appear as round or oval, yellowish-grey ulcers with surrounding erythematous “halo.” They can be located on any mucous membrane, but are most commonly noted on the buccal mucosa. Etiology of aphthous ulcers is unknown, but they may be infectious, autoimmune, allergic, nutritional, or traumatic in nature. Aphthous ulcers are more common in individuals with inflammatory bowel disease, celiac disease, immunosuppression, cyclic neutropenia, rheumatologic disorders (eg, juvenile rheumatoid arthritis, systemic lupus erythematosus), or nutritional deficiencies ( $B_{12}$ , folate, iron, zinc). Aphthous ulcers present in 3 ways—as minor aphthous ulcers, major aphthous ulcers, and herpetiform ulcers. Minor aphthous ulcers are the most common form, accounting for 80% of cases, and are characterized by small (2–5 mm) lesions that last 5 to 12 days and heal without scarring. Major aphthous ulcers are larger in diameter (up to 1 cm), can take several weeks to heal, and may scar. Herpetiform ulcers are the least common type of aphthous ulcers, accounting for less than 10% of cases. These are very painful, multiple 1- to 2-mm papules, vesicles, or ulcers that are grouped together and can coalesce to form a larger lesion. Treatment for all types of aphthous ulcers is supportive, with bland diet. Topical anesthetic creams, topical steroid creams, or mouth

rinses can be tried, but the benefits are not well established. Recurrence is likely.

### Mucocoele/Ranula

A mucocoele is a translucent or blue pseudocyst resulting from accumulation of mucous behind a traumatized minor salivary gland. Mucocoeles are usually painless, located on the lower lip or buccal mucosa, and range from very small to several centimeters in size. They are usually 1 cm or less in diameter, but can fluctuate in size. Mucocoeles are among the more common pediatric oral lesions, accounting for 11.6% to 24.5% of all pediatric oral biopsies. Mucocoeles generally require no treatment; many resolve spontaneously. If the lesion is large or uncomfortable, excision may be warranted.

Ranulas are a type of mucocoele that result from blockage of a larger salivary duct located on the floor of the mouth, resulting in a unilateral collection of mucous under the tongue. Unlike other mucocoeles, ranulas require marsupialization surgical excision because they are likely to become large and may interfere with swallowing, mastication, speech, or breathing. Mucocoeles commonly recur.

### Angular Cheilitis

Angular cheilitis, also known as angular stomatitis and perleche, is inflammation at the corners of the mouth that manifests as erythema, fissures, erosions, and discomfort. Common triggers include lip licking and sensitivity to a topical compound applied to the lips. Less commonly, persistent angular cheilitis is caused by a nutritional deficiency (riboflavin or iron). Primary or secondary infection with *Staphylococcus* or *Candida* is quite common, so treatment includes topical yeast treatment (Nystatin) and topical antibiotic agents (Mupirocin), with or without low-dose topical steroids. Pediatricians should encourage use of thick emollient application, good oral hygiene, and trigger avoidance.

### Benign Migratory Glossitis

Benign migratory glossitis, more commonly known as “geographic tongue,” results from loss of the filiform papillae on discrete areas of the tongue, making it look smooth, red, and shiny. Areas of depression are most commonly noted on the dorsum and lateral aspects of the tongue, and the location and pattern vary over time, so it seems to “migrate.” There is no effect on ability to taste, but some children report tongue irritation with spicy or acidic foods. Benign migratory glossitis affects about 1% of children; its cause is unknown. The condition is self-limiting, with waxing and waning. No treatment is necessary, as benign migratory glossitis does not cause harm, nor is it associated with any medical issues. Reassurance should be provided. In contrast, complete atrophic glossitis involving the entire tongue can be associated with underlying systemic conditions, especially autoimmune disorders (eg, celiac disease) or deficiencies in nutrients such as iron, folate, or  $B_{12}$ .

### Gingival Hyperplasia

Gingival hyperplasia in children can be hereditary or result from medications, inflammation, or infiltration.

- Hereditary or idiopathic hyperplasia. This is a rare, progressive enlargement of all the gingiva that begins in early childhood.
- Inflammatory. Chronic gingivitis can trigger gingival overgrowth in a general or localized pattern. Inflammatory hyperplasia often resolves when the plaque and gingivitis are adequately controlled.
- Infiltrative. Leukemic cells can infiltrate the gingival tissues and cause gingival hypertrophy. This condition is most often seen in acute monocytic leukemia and is characterized by inflamed, friable gingiva that bleeds easily.
- Drug-induced. Medications can also cause hyperplasia. Common offenders include phenytoin, calcium channel blockers (eg, nifedipine), and cyclosporine. The gingival enlargement is fibrous, and, therefore, neither painful nor very prone to bleeding.

Gingival hyperplasia can interfere with oral hygiene, tooth eruption, and chewing, and can cause gingivitis. Treatment of gingival hyperplasia includes meticulous oral hygiene to minimize inflammation and discontinuing any offending medication. Gingivectomy should be considered if the hyperplasia is severe, especially with hereditary gingival hyperplasia.

### Enamel Defects

Enamel is a protective layer on the visible part of the crown of the tooth. It is the hardest and most highly mineralized substance of the body. The formation of enamel is very sensitive, and disturbances during the tooth development can result in enamel defects of the primary or permanent teeth. Enamel defects can appear as pitted, rough surfaces or as white, yellow, or brownish discoloration of a single tooth or multiple teeth. A tooth with an enamel defect can be considered “weak,” with reduced thickness and poor enamel quality. Teeth with enamel defects are more prone to increased sensitivity, wear, fracture, and increased risk of dental caries. Many risk factors for enamel defects in primary and permanent teeth have been identified in children. Common risk factors include adverse maternal health events during pregnancy (illnesses, nutritional deficiencies, medications), birth difficulties (prematurity, hypoxia), early childhood illnesses (high fever, pneumonia, middle ear infection, viral infections), poor childhood nutrition (diet deficient in calcium, phosphate, or vitamins A, C, or D), and trauma to the mouth or primary teeth before the age of 4 years. Rarely, enamel defects can be inherited and affect all the teeth in both dentitions. This condition is called amelogenesis imperfecta.

Children with enamel defects should be evaluated by a dentist. The aim of treatment is to reduce tooth sensitivity, strengthen teeth, and improve tooth appearance. The type of treatment required will depend on the severity and symptoms of the enamel defect and may include fluoride varnish for sensitivity and strengthening, dental restoration with a tooth-colored resin or crown, or even extraction for severely affected teeth.

### Dental Acid Erosion

In the past decade, dental erosion has become more of a concern in the pediatric population globally. The

prevalence of acid erosion of the dentition among a sample of 11- to 13-year-old children was 41% in the United States and 37% in the United Kingdom. The World Health Organization has adopted Pindborg’s definition of dental erosion as “the progressive irreversible loss of dental hard tissue that is chemically etched away from the tooth surface by extrinsic and/or intrinsic acids by a process that does not involve bacteria; which differentiates it from dental caries process.” Extrinsic causes of tooth erosion include acidic drinks, foods, and candies. Gastric acid is the most common intrinsic cause of dental erosion as a manifestation of gastroesophageal reflux disease or bulimia. The exposure of the tooth structure to an acid source with a pH below 4 will result in erosion. The titratable acidity is the amount of available acid or the erosion potential of the dietary source, reflecting the amount of alkali needed to neutralize an acid. For example, orange juice has a pH of 3.8 and a titratable acidity index of 4.5 reflecting high erosion potential compared to the low erosion potential of sparkling water with a pH of 5.3 and titratable acidity of 0.1. Various teeth and tooth surfaces will be affected by the acidic dietary trigger and by eating behavior. The anterior teeth (incisors) are predominantly affected by frequent consumption of acidic drinks, swishing or mouth holding of acidic drinks, or exposure to the emesis associated with bulimia. The posterior teeth (molars) are affected mainly by mastication of acidic foods as well as by gastric acid exposure from gastroesophageal reflux disease (GERD) and severe cases of bulimia. Treatment of dental acid erosion involves identifying and removing or reducing the acid source. If the enamel loss is causing sensitivity, dental restorative care is indicated.

## Chapter 241 DIABETES MELLITUS

Asma Javed, MBBS; W. Frederick Schwenk II, MD;  
Peter Tebben, MD

Diabetes mellitus consists of a heterogeneous group of conditions with diverse underlying pathophysiologic factors that result in defects in insulin secretion or action, leading to elevated blood glucose levels. Although altered glucose metabolism is the most prominent abnormality, fatty acid and protein metabolism are also regulated by insulin. Diabetes mellitus is currently classified into 4 types, the 2 most common of which are type 1 and type 2 diabetes (T1D and T2D). T1D is further divided into type 1A, which is immune mediated, and type 1B, which is typically idiopathic. The remaining forms are gestational diabetes and “other” causes of diabetes, such as genetic defects in  $\beta$ -cell function or insulin action, diseases of exocrine pancreas (eg, cystic fibrosis), and drug- or chemical-induced diabetes. Type 1 diabetes refers to conditions that result in an elevated blood glucose level caused by an absolute insulin deficiency, whereas T2D results from progressive insulin secretory defect in the setting of insulin resistance.

### INCIDENCE

The incidence of T1D in the United States has been estimated at approximately 12 per 100,000 person-years for individuals younger than 20 years. Certain ethnic groups such as individuals from Northern European countries have a much higher risk than individuals from most Asian countries. Several authors have documented that the worldwide incidence, including the United States, of T1D has been increasing. The cause of this global increase in T1D is not known.

Historically, T2D contributed to only a fraction of the total number of children diagnosed with the disease, but with obesity as a strong correlate, the incidence of T2D has risen significantly in recent years, especially among certain ethnic groups, such as African Americans, Hispanics, and Native Americans.

### ETIOLOGY

#### Type 1 Diabetes

Type 1 diabetes results from T-cell-mediated destruction of insulin-producing  $\beta$  cells in the pancreatic islets of Langerhans. Although its precise cause is unknown, T1D occurs in genetically susceptible subjects, and the process is likely triggered by one or more environmental agents. Concordance rates for monozygotic twins have ranged from 17% to 50%, significantly higher than concordance rates reported in dizygotic twins or nontwin siblings of individuals with T1D. These rates likely underestimate the lifetime risk for developing diabetes because the patients were only followed for a finite period. Studies using life-table analysis have predicted significantly higher concordance among monozygotic twins.

#### Genetic Factors

Many genes have been implicated in conferring genetic susceptibility to T1D, but the strongest associations have been found with the genes encoding human leukocyte antigen (HLA) molecules on chromosome 6p. Individuals with T1D express the HLA DR3-DQ2/DR4-DQ8 genotype at a significantly higher rate than the general population. Furthermore, a monozygotic twin without diabetes expressing DR3-DQ2/DR4-DQ8 whose twin has diabetes is at significantly higher risk for developing the disease than twin pairs without this genotype. Other HLA molecules seem to offer protection against the development of diabetes. The notion that offspring of fathers with T1D are more likely to develop diabetes than offspring of mothers with T1D has also been suggested. Several other genes and chromosomal regions have been implicated in the development of T1D. These data clearly show that the development of T1D has a genetic component, although genetic susceptibility is not solely responsible.

#### Environmental Factors

Environmental exposures have been implicated in the development of T1D in genetically susceptible individuals. Viral infections have long been considered to play a role, but many of the data are conflicting. However, congenital rubella syndrome has consistently been shown to confer added risk for the development of T1D. A link between childhood immunizations and

several autoimmune disorders, including T1D, has been postulated. This association was explored in a large study from Denmark that included almost 740,000 children and 4.7 million person-years of follow-up and found no association between T1D and immunization status.

### Dietary Factors

Dietary factors such as duration and timing of breast-feeding, introduction of cow's milk, timing of introduction of cereals to the diet, gluten, and nitrate exposure have also been implicated, but definitive data are lacking. Although conclusive evidence does not exist, an association between vitamin D repletion and protection from development of T1D has been suggested. Too little information is available regarding dietary antigen exposure to make definitive recommendations regarding introduction of certain foods to infants and children in an attempt to prevent T1D.

### Antibodies

The autoimmune nature of T1D is supported by the high rate of detectable antibodies against pancreatic islet cells in patients recently diagnosed with T1D. These antibodies are usually present long before the clinical onset of disease. Antibodies against islet cell antigens, glutamic acid decarboxylase, and insulin have all been used to predict progression to diabetes in high-risk individuals with HLA susceptibility or a family history of diabetes. Whether these antibodies are causal or simply a marker of disease is unclear. Although routine clinical use of antibody measurement for the prediction of development of T1D is controversial, it may be of use in initial diagnosis of T1D. T1D is also associated with other autoimmune conditions such as celiac disease, thyroid disease, adrenal insufficiency, and polyglandular autoimmune failure.

### Type 2 Diabetes

In contrast to T1D, T2D is caused by a relative insulin deficiency, peripheral resistance to its action, or both. The increase in childhood T2D has paralleled the marked rise in childhood obesity, which has prompted many communities, public health organizations, and medical societies to initiate programs to treat and prevent childhood obesity. The American Academy of Pediatrics (AAP) has published a policy statement regarding the prevention of pediatric obesity. The AAP offers practical guidelines for early identification and intervention in high-risk children. Several studies have demonstrated that most children or adolescents with T2D are obese, have clinical evidence of insulin resistance (acanthosis nigricans), or have a significant family history of T2D. These characteristics should prompt the primary care physician to screen a child for diabetes. The American Diabetes Association (ADA) has published a consensus statement regarding T2D in children and adolescents, including recommendations for screening individuals from high-risk populations, which is also endorsed by the AAP (Box 241-1). The ADA recommendations focus on overweight and obese children because most cases occur in this patient population. Additionally, identification of at-risk

#### BOX 241-1 Criteria for Screening High-Risk Children for Diabetes

Overweight (body mass index >85th percentile for age and sex), **AND** any 2 risk factors:

- Family history of type 2 diabetes in a first- or second-degree relative
- High-risk race or ethnicity (Native American, African American, Latino, Asian American, and Pacific Islander)
- Signs of insulin resistance or associated conditions:
  - Acanthosis nigricans
  - Hypertension
  - Dyslipidemia
  - Polycystic ovarian syndrome
  - Small for gestational age
- Maternal history of diabetes or gestational diabetes

Age to initiate screening:

- 10 years, **OR**
- Onset of puberty if younger than 10 years

Frequency: every 3 years

Preferred screening test: plasma glucose after an 8-hour fast

#### BOX 241-2 Criteria for the Diagnosis of Diabetes

- Symptoms of diabetes (polyuria, polydipsia, and unexplained weight loss) and a casual<sup>a</sup> plasma glucose of 200 mg/dL or greater, **OR**
- Fasting plasma glucose of 126 mg/dL or greater (fasting for at least 8 hours), **OR**
- Plasma glucose of 200 mg/dL or greater 2 hours after an oral glucose challenge. Glucose load should contain 75 g of glucose for adults or 1.75 g/kg in children<sup>b</sup> (maximal dose of 75 g), **OR**
- HbA1c of 6.5% or more

<sup>a</sup>Casual: any time of day without regard to time of last meal.

<sup>b</sup>A dose of 1.75 g/kg of glucose has been suggested when performing an oral glucose tolerance test in children, but this dose is less well established than the 75-g dose used in adults.

Adapted from American Diabetes Association. Standards of medical care in diabetes—2014. *Diabetes Care*. 2014;37(Suppl 1):S14–80. Copyright © 2014 American Diabetes Association. Reprinted with permission.

children requires only the calculation of the body mass index, which can be performed quickly and inexpensively. However, these recommendations are based on few data, and clinical judgment may need to supersede strict adherence to these guidelines. Measurement of a fasting plasma glucose level is the suggested screening tool in children at high risk for developing diabetes because it is simple to perform and inexpensive, but other methods may be appropriate in establishing the diagnosis (Box 241-2).

**Maturity-Onset Diabetes of the Young**

Monogenic forms of diabetes include a group of rare disorders known as maturity-onset diabetes of the young (MODY) (Box 241-3). These disorders likely represent between 2% and 5% of all cases of diabetes. The clinical course can range from mild to progressive disease with the development of microvascular complications. MODY is often misclassified as T1D or T2D and should be suspected if there is a family history suggestive of autosomal-dominant inheritance, especially if diabetes develops at a young age in a thin individual and there is a lack of autoimmunity based on antibody testing. Because the clinical course and treatment vary considerably among the different forms of MODY, the specific type of MODY should be characterized if the diagnosis is made or suspected. An in-depth discussion of these infrequent forms of diabetes is beyond the scope of this chapter; however, recent reviews can provide additional information.

**DIAGNOSIS**

The ADA has outlined several ways to diagnose diabetes based on a patient's symptoms and plasma glucose concentration (see Box 241-2). The diagnosis can be established in a child who has symptoms consistent with diabetes (polyuria, polydipsia, unexplained weight loss) and a casual plasma glucose level of 200 mg/dL or greater. The ADA has defined *casual* as any time of day without regard to time since the last meal. T1D is usually diagnosed by these criteria and has a relatively acute-subacute onset of symptoms (days to weeks). T2D is more insidious than T1D in onset, and patients are typically overweight and may have signs of insulin resistance, including acanthosis nigricans and elevated lipid levels. Whereas most patients with T1D are symptomatic at the time of diagnosis, individuals with T2D can be asymptomatic, and the diagnosis may often be the result of screening. This fact highlights the need for identification of high-risk individuals in an effort to prevent or postpone diabetes or intervene early in the disease.

A plasma glucose level of 126 mg/dL or greater after an 8-hour fast will establish the diagnosis and is a simple test to perform in the outpatient setting. Diabetes can also be diagnosed using an oral glucose tolerance test, with a cutoff of 200 mg/dL 2 hours after the glucose load being diagnostic of diabetes. This method is more costly and labor intensive but may identify some individuals with diabetes who have a fasting plasma glucose level less than 126 mg/dL.

## DIFFERENTIAL DIAGNOSIS

Hyperglycemia has many causes other than diabetes that should be considered when an elevated plasma glucose concentration is found (see Box 241-3). A thorough history, physical examination, and review of the patient's medications are often sufficient to determine the cause of hyperglycemia. The precise origin of hyperglycemia should be sought for each child to tailor therapy specific to the underlying pathophysiologic condition.

It can be difficult to differentiate between T1D and T2D in some cases. Although insulin therapy may not always be necessary for children with T2D, it is a safe and effective choice if it is not initially clear whether the patient has T1D or T2D. If excess glucocorticoids or other medications cause diabetes, dose reduction or elimination of the drug (if possible) may be all that is required.

## EVALUATION

### Pertinent History

Hyperglycemia from any cause can lead to symptoms related to an osmotic diuresis. Polyuria and polydipsia occur as a result of the loss of glucose in the urine as the plasma concentration exceeds the renal threshold for glucose reabsorption ( $\approx 180$  mg/dL), although glucose may be seen in the urine of some normoglycemic individuals. Glycosuria alone cannot be used for the diagnosis of diabetes because several other conditions, including renal injury, lead to glycosuria. Because of this glycosuria, the child with T1D or T2D loses calories, which manifests as weight loss in the face of an increased appetite. Depending on the timeliness of diagnosis of diabetes, particularly T1D, symptoms of nausea and abdominal pain may develop from metabolic acidosis caused by ketone body buildup from use of adipose tissue as fuel.

Although an infrequent occurrence in T2D, diabetic ketoacidosis (DKA) has been reported, and the presence of ketosis cannot always reliably distinguish between T1D and T2D. If severe hyperglycemia and metabolic acidosis are left uncorrected, neurologic sequelae, including seizures and coma, may occur. Recognizing the early symptoms of diabetes may help prevent severe DKA and potentially fatal outcomes. T1D can occur at any age, including in the neonatal period. With the rise in childhood obesity, T2D is occurring in younger children, although children who develop T2D most commonly do so during puberty, a period of relative insulin resistance.

### Physical Examination

No pathognomonic physical findings are associated with T1D or T2D. Particularly in the case of T1D, because it has an acute-subacute onset, physical examination findings such as signs of dehydration, weight loss, or tachycardia may be present commensurate with the duration and severity of hyperglycemia and metabolic acidosis. If moderate or severe ketoacidosis is present, tachypnea and a characteristic *fruity* odor to the breath caused by the ketosis may be noted. Altered mental status or seizures may occur in severe DKA.

The typical patient with T2D will often have polyuria and polydipsia. Weight loss may also be apparent, but patients are invariably obese at the time of diagnosis. Many children with T2D have acanthosis nigricans that is a result of their insulin resistance and may be hypertensive.

### Laboratory Studies

In the appropriate clinical setting, a few basic laboratory studies are usually sufficient to differentiate between T1D and T2D. Irrespective of the type, diabetes can be diagnosed using the criteria adopted by the ADA (see Box 241-2). Hyperglycemia and glycosuria are the predominant features in both conditions. Significantly elevated blood and urine ketone levels are traditionally associated with T1D but are occasionally present in patients with T2D. Additional laboratory abnormalities associated with DKA are discussed in Chapter 354, Diabetic Ketoacidosis. Insulin and C-peptide concentrations are generally low in patients with established T1D compared with the elevated concentrations in patients with T2D. Severe DKA is seen less frequently in T2D.

Although certain HLA haplotypes are associated with an elevated risk for T1D, they play no role in the diagnosis. Most children with T1D have antibodies directed against insulin or pancreatic islet cell antigens at the time of diagnosis. Although these antibodies can be elevated in children who may not develop disease for many years or never develop diabetes, they can be useful in making or confirming the diagnosis of T1D.

As pancreatic  $\beta$ -cell function declines and endogenous insulin secretion diminishes, C-peptide concentrations fall. Plasma C-peptide concentrations that are very low or undetectable in the face of hyperglycemia are consistent with the diagnosis of T1D. However, C-peptide concentrations are often not helpful at the time of diagnosis because endogenous insulin (and thus C-peptide) production has not completely failed. Low C-peptide concentrations can be seen in MODY or T2D with glucose toxicity, which may make it less helpful at time of diagnosis.

## MANAGEMENT

### Type 1 Diabetes

The clinical management of T1D requires an integrated multidisciplinary team consisting of physicians, nurses, diabetes educators, dietitians, social workers,

and psychologists. Patients and families must be adequately educated and supported to safely achieve as near euglycemia as possible because of the unequivocal evidence that tight glucose control prevents complications of diabetes. Because a sizable portion of a child's day is spent in school, close communication with school or child care personnel is essential for optimal diabetes management. Without adequate education, safe and successful diabetes management is difficult to attain. The education should be tailored to provide developmentally appropriate participation by the child. Teenagers should be able to assume more responsibility for their care than toddlers. Although improved glycemic control improves outcomes with regard to microvascular and macrovascular complications, these benefits do not come without risk. The main risk posed in achieving near euglycemia is increased frequency and severity of hypoglycemia. In the Diabetes Control and Complications Trial (DCCT), the rate of severe hypoglycemia in the intensive insulin group was 62 events per 100 patient-years compared with 19 events per 100 patient-years in the conventional group. Most long-term trials showing improvement in chronic complication rates have been performed in adults. However, a part of the Epidemiology of Diabetes Interventions and Complications (EDIC) trial evaluated the adolescent patients who were initially enrolled in the DCCT (13 to 17 years of age at enrollment). At the end of the DCCT, the intensive treatment group had significantly lower HbA1c values, but this effect was lost during the 4-year EDIC follow-up of this cohort. Despite the patients having similar control of their diabetes by the end of the study, those previously treated intensively had a marked reduction in the progression of diabetic retinopathy, which suggests that tight glycemic control is important even in this adolescent population.

Several models of successful diabetes education programs exist, but all are centered on the goal of achieving as close to euglycemia as possible while minimizing adverse events, primarily hypoglycemia. The ADA has proposed age-adjusted guidelines regarding target blood glucose values and targets for HbA1c (Table 241-1). Less tight control is recommended for younger children in whom the risks for hypoglycemia may be greater and the advantages of very tight control have not been proved. Postprandial

glucose targets are widely used in the management of diabetes during pregnancy. However, these targets are not commonly used outside pregnancy because their value has not been studied rigorously in children. These goals are suggested, and individualized goals may be necessary. Lower HbA1c values may be safely obtained in select patients in whom the risk for severe hypoglycemia is deemed low. However, the lower the HbA1c level, the higher the risk for severe hypoglycemia (Figure 241-1).

### Type 2 Diabetes

The treatment options available for patients with T2D are more diverse. Although many effective medications with a variety of mechanisms of action are available, few are indicated for the treatment of T2D in children. The type of therapy must be tailored to fit the clinical situation of the patient. If diabetes is discovered in an asymptomatic patient with a normal or near-normal HbA1c level, lifestyle modification,

**Figure 241-1** Increased risk for severe hypoglycemia with lower HbA1c. (From Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med.* 1993;329(14):977-986. **Table 241-1**

**American Diabetes Association Guidelines for Glycemic Control in Children and Adolescents**

AGE (YR)	PLASMA GLUCOSE (MG/DL)		HBA1c (%)
	PREMEAL	BEDTIME OR OVERNIGHT	
0-6	100-180	110-200	8.5
6-12	90-180	100-180	8.0
13-19	90-130	90-150	7.5
Adults	90-130	—	7

Adapted from American Diabetes Association. Standards of medical care in diabetes—2014. *Diabetes Care.* 2014;(Suppl 1):S14-80. Copyright © 2014 American Diabetes Association. Reprinted with permission.

including medical nutrition therapy, may be the most appropriate treatment. Weight loss and exercise can significantly improve insulin sensitivity in the setting of T2D. These approaches may be adequate for maintenance of glycemic goals in individuals willing to participate regularly in physical activity and modify their eating behaviors. The Diabetes Prevention Program found that lifestyle modification intervention reduced the development of T2D in adults by 58% over the 2.8 years of follow-up. In the recently completed Treatment Options for Type 2 Diabetes in Adolescents and Youth (TODAY) trial to maintain glycemic control in youths with T2D, metformin therapy alone achieved durable glycemic control in only about half of the adolescents enrolled.

In addition to lifestyle changes, metformin should be considered first-line pharmacologic therapy for children with T2D. However, when a patient is experiencing symptomatic hyperglycemia and has a significantly elevated HbA1c (>8% to 9%), insulin therapy is usually required. In many instances, children with T2D are able to improve their glycemic control with less intensive programs than are needed for patients with T1D; once- or twice-daily, intermediate- or long-acting insulin may be sufficient. Lifestyle intervention and medical nutrition therapy remain the cornerstone of treatment.

The United Kingdom Prospective Diabetes Study (UKPDS) showed that improvements in HbA1c levels in adults with T2D improved outcomes with respect to microvascular complications, highlighting that good glycemic management is equally important for T2D as for T1D. The only oral agent approved for use in children is metformin. Metformin is approved for children 10 years of age and older with T2D. It has the advantage of not inducing hypoglycemia when used as monotherapy and is also associated with weight stabilization or mild weight loss. The major side effect of metformin is gastrointestinal disturbance, which can be largely prevented by slowly titrating the dose. It should not be used in patients with significant liver disease or renal impairment.

## INSULIN

### Insulin Programs

With the availability of multiple forms of insulin (Table 241-2), many options exist for designing an insulin regimen for each patient. All patients will need to have an individualized plan with respect to the type and dose of insulin, timing of injections, and appropriate frequency of home glucose monitoring, depending on their daily routine. No single program will be acceptable for every patient. As patient needs and technology change, programs should be updated to maintain glycemic goals. Typical doses of insulin in children range from 0.5 to 1 unit of insulin per kilogram per day. However, during puberty, because of insulin resistance, children usually require higher insulin doses to achieve the same control.

The 3 most commonly used insulin programs are split-mixed, multiple daily injection (MDI), and continuous subcutaneous insulin injection (CSII). Each program should be designed to mimic human physiology such that even in the fasting state, insulin is normally produced and secreted by the pancreas to maintain euglycemia (basal insulin). During a meal, additional insulin is secreted from the pancreas as the blood glucose level begins to rise when carbohydrate is absorbed from the intestinal mucosa (bolus insulin). Therefore, for patients with T1D, a basal bolus regimen of insulin should be followed whereby intermediate- or long-acting insulin is used as the basal insulin, and a short-acting insulin bolus is used to control the postmeal glucose rise (Figure 241-2).

### Split-Mixed Program

A split-mixed program can be used in younger patients in whom fewer injections may be desirable. A short-acting and an intermediate-acting insulin are mixed and given as a single injection before breakfast and again before the evening meal. Considerably higher doses are generally required in the morning compared with the evening. A typical ratio would be two-thirds to three-fourths of the total daily dose

**Table 241-2** Onset, Peak, and Duration of Action of Currently Available Insulin

	ONSET	PEAK	DURATION
<b>SHORT ACTING</b>			
Regular	30 min	2–4 hr	4–6 hr
Lispro	<15 min	1 hr	3–4 hr
Aspart	<15 min	1 hr	3–4 hr
Glulisine	<15 min	1 hr	3–4 hr
<b>INTERMEDIATE ACTING</b>			
NPH	2–4 hr	4–6 hr	10–16 hr
Lente	3–4 hr	6–10 hr	10–20 hr
<b>LONG ACTING</b>			
Glargine	2–3 hr	None	≥24 hr
Detemir	1–2 hr	3–9 hr <sup>a</sup>	6–23 hr <sup>a</sup>

<sup>a</sup>Higher doses result in delayed peak and longer duration of action.

**Figure 241-2** Bolus insulin is used to maintain blood glucose in the goal range after a meal. Basal insulin is used to maintain blood glucose in the goal range between meals and overnight.

given in the morning and the remainder in the evening. Approximately two-thirds of the morning dose is intermediate-acting insulin, and the rest is short acting. Equal amounts of intermediate- and short-acting insulin are given with the evening meal. A snack at bedtime can prevent nighttime hypoglycemia because the intermediate-acting insulin can peak in the early morning hours. Although many patients like this program because only 2 shots are required daily, achieving adequate glycemic goals is sometimes not possible. The regimen is acceptable for young patients in whom the frequency of injections is ideally kept to a minimum and glycemic targets are also not as stringent as in adolescents and adults. A split-mixed program also requires patients to be on a fixed diet with respect to timing and nutrient content at each meal in an attempt to match consistently the insulin dose with the time and amount of food eaten. Because of these limitations, patients are often changed to or started on a more intensive insulin program (MDI or CSII).

### Multiple Daily Injection Program

The MDI program consists of intermediate- or long-acting insulin as the basal insulin and short-acting insulin as a bolus with each meal. In contrast to a split-mixed program, MDI requires 3 or 4 (or more) injections each day. This program offers more flexibility with regard to timing and content of meals than split-mixed programs. Basal insulin constitutes approximately one-half of the total daily dose and is usually given in the evening. The amount of short-acting insulin given with each meal will depend on the amount of carbohydrate consumed at that meal. If the patient has been prescribed an exchange diet with a fixed amount of carbohydrate for each meal, then the dose of insulin will be the same from day to day. However, many patients will choose to vary the amount of carbohydrate at each meal within an overall meal plan and will adjust their insulin according to the amount of carbohydrate consumed. This regimen also employs a correction dose of short-acting insulin if the premeal glucose is outside the target range.

### Continuous Subcutaneous Insulin Injection Program

Insulin pumps have improved significantly since they were first introduced. The initial pumps were large and heavy, with few safety features. Today's pumps are considerably smaller and can be concealed under a person's clothing. A cartridge filled with short-acting insulin serves as both the basal and bolus insulin. Multiple basal rates can be programmed for patients whose basal insulin requirements are not constant throughout the day. This feature is not available with a split-mixed or MDI program. The insulin is delivered through tubing that is connected to a flexible plastic cannula inserted subcutaneously. The tubing and cannula are changed every 2 to 3 days, significantly reducing the number of injections required. Many, but not all, studies suggest there may be a slight improvement in HbA1c in patients treated with CSII compared with MDI. Doyle and colleagues performed a randomized, prospective trial in children comparing CSII (aspart) to MDI (glargine and aspart). These authors found a significant reduction in HbA1c at the end of 16 weeks in the CSII group compared with the MDI group (7.2% vs 8.1%, respectively). In the recently completed longest follow-up study of children treated with insulin pumps, with mean duration of follow-up of 3.5 years, insulin pump therapy was associated with a sustained improvement in glycemic control and with reductions of severe hypoglycemia and hospitalization for DKA compared with a matched cohort using injections.

Current insulin pumps contain numerous safety features that minimize the previous concerns of malfunction seen with earlier-generation pumps. In addition, newer pump technology has begun to combine CSII with continuous glucose monitoring. No long-term data are available to suggest that microvascular or macrovascular complications are reduced with CSII compared with MDI. The goals of therapy should be the same despite the insulin program used (see Table 241-1).

### Monitoring and Adjusting

Appropriate insulin dosing cannot be accomplished without adequate blood glucose monitoring because there is a strong correlation between frequency of monitoring and glycemic control. The glucose values must be recorded in a log and reviewed on a regular basis to determine whether insulin doses need to be adjusted. The data from many home glucose meters and insulin pumps can be transferred to a computer to assist in tracking glycemic control. For patients with T1D and some patients with T2D treated with insulin, blood glucose concentrations should be monitored before meals, at bedtime, and occasionally at night. For individuals with T2D treated with lifestyle modification or oral agents, less frequent monitoring is required. Additional glucose determinations may be needed during illness or exercise, or with symptoms of hyperglycemia or hypoglycemia. Many good home glucose monitors are available. All of these monitors should be checked periodically for accuracy, and patients should receive training on proper technique.

Adjusting insulin doses is necessary to maintain good glycemic control. The glucose log serves as a guide to making appropriate changes. Because many variables exist that cannot be accounted for, patients should be informed that their blood glucose concentration will not always fall in the normal range. For some people, this circumstance can be discouraging and lead to improper insulin adjustments. For others, lack of education or fear of hypoglycemia leads to improper dose adjusting.

When discussing insulin doses in the context of hypoglycemia or hyperglycemia, physicians must be clear about the difference between insulin adjustments and corrections. Insulin doses are adjusted based on patterns of blood glucose concentrations recorded in the log. The purpose of an adjustment is to prevent future abnormal glucose levels. Physicians should commonly ask patients to look for a trend of hyperglycemia over at least several days before making an adjustment. For example, if a patient consistently has glucose values before their evening meal that are higher than the goal range, an increase in the short-acting insulin before the noon meal would need to be made.

Because patients will often have a glucose concentration fall outside their goal range, corrections are used to rectify this situation. A correction is used to address a glucose concentration that is currently abnormal. For example, if a patient has a blood glucose level that is below the goal range before breakfast, then insulin would be subtracted from their morning bolus dose of short-acting insulin. If the glucose is above the goal range, then correction insulin may be added to the bolus dose of short-acting insulin at that meal to correct the hyperglycemia. The correction is used to remediate the abnormal glucose, whereas the bolus dose of short-acting insulin is used to account for the food that will be eaten at a meal.

### Meal Plan

One of the major determinants of blood glucose concentration is carbohydrate ingestion. Matching the amount of food intake with the appropriate amount of insulin requires knowledge of the onset, peak, and duration of action of the various types of insulin available (see Table 241-2).

Many meal plans have been used in the care of patients with diabetes to optimize glycemic control. Although a particular diabetes program may advocate one meal plan over another, comparative trials showing that one is superior to another are lacking. As children grow and vary their activity levels, caloric requirements can change significantly. Advice from a dietitian experienced in the management of children with diabetes is necessary for the implementation of any successful diabetes program. Commonly used meal plans include a consistent carbohydrate or exchange diet and carbohydrate counting. These plans require specific education to ensure that patients are able to assess the nutrient content of the foods they eat and how this factor affects the management of their disease.

A consistent carbohydrate or exchange diet requires a patient to eat a consistent amount of nutrients

at each meal from day to day. For example, a patient may be prescribed 45 g of carbohydrate for breakfast, 60 g for lunch, and 60 g for dinner. The patient would be expected to eat according to this pattern each day. The amount of fat and protein may also be prescribed for each meal. Foods are categorized according to nutrient content, and this list is used to create a meal. Foods with equivalent nutrient content can be *exchanged* for each other to introduce variety in the diet. Snacks are usually incorporated into this diet depending on the individual patient's needs and preferences. The advantage of this diet is that nutrient intake is consistent, allowing insulin dosing to also be consistent. This diet can be used for patients on split-mixed, MDI, or CSII programs.

Carbohydrate counting is a more complex but increasingly popular option. This diet would not be appropriate for patients on a split-mixed insulin program because nutrient intake may vary substantially from meal to meal and day to day. Insulin doses in a split-mixed program cannot easily be adjusted to account for the dietary variability of carbohydrate counting. However, this diet can be used for patients on an MDI or CSII insulin regimen. For this meal plan, patients must also be familiar with the carbohydrate content of each food they eat. For each unit of carbohydrate taken, a certain amount of insulin must be given to maintain euglycemia. A typical ratio may be 1 unit of short-acting insulin for each 15 g of carbohydrate eaten. This ratio is adjusted for each patient and may even vary based on time of day for a given individual. Carbohydrate counting has the advantage of being able to vary the amount of food at a meal according to how much the patient desires to eat. Because patients are able to take more insulin to maintain glycemic control while overeating, carbohydrate counting must be a part of an overall meal plan so that overeating does not lead to obesity or contribute to hyperlipidemia. As long as healthy, well-balanced eating is maintained, carbohydrate counting offers an alternative to the exchange diet, with more flexibility in the timing and content of each meal. Carbohydrate counting requires specific education and a motivated patient and family to be implemented correctly.

### Exercise

Exercise can be performed safely, and children should not be discouraged from participating in sports simply because they have diabetes. Attention to the effects of activity on glucose levels can assist in preventing hypoglycemia during or after exercise. Because exercise may alter the absorption of subcutaneous insulin and can enhance insulin sensitivity, hypoglycemia may occur if changes are not made in the amount of food eaten or insulin taken. Two methods have been developed for preventing hypoglycemia during planned physical activity. The dose of short-acting insulin given at the previous meal might be reduced, or a snack can be given just before or during the activity. If the activity is not planned, then a snack will be the only option. The blood glucose level should be checked before and again after exercise to determine the effect of the activity on glucose concentrations. If the activity

is prolonged (>45 to 60 minutes), the blood glucose level should also be checked periodically during the activity. Only by documenting the effect of exercise on an individual's glucose level can appropriate decisions be made to prevent hypoglycemia. Checking a nighttime blood glucose level is advised when prolonged activity has taken place, especially in the evening. The effect of exercise may be sustained and lead to delayed hypoglycemia.

### Illness

Parents and patients need to be aware that illness can have a notable effect on blood glucose values. Hypoglycemia or hyperglycemia may result, depending on the severity of the illness and the amount of food eaten. A common error made is the omission of insulin injections because the child is not eating. Regardless of food intake, insulin is necessary in health or illness. Although the dose may change, some insulin should be given even if the child is not able to eat. Some practical guidelines can assist in appropriate care during illness:

1. Never completely omit insulin. Insulin requirements may increase.
2. Monitor and record blood glucose concentrations every 2 to 4 hours.
3. Monitor urine ketone concentrations frequently, even if the blood glucose level is not significantly elevated (>250 mg/dL). Some patients with T1D can develop ketosis in the absence of hyperglycemia when ill.
4. Encourage adequate hydration.

By following these simple guidelines, most children with minor illnesses can avoid hospitalization and emergency department visits. They will need to be seen if they have persistent moderate or large urine ketone levels, are unable to treat hypoglycemia effectively, or become significantly dehydrated.

## COMPLICATIONS

Before the discovery of insulin, T1D was a fatal disease. Progressive metabolic abnormalities, including ketoacidosis, would eventually lead to death. With the availability of insulin for clinical use beginning in the early 1920s, patients were able to survive the more immediate threat of severe acidosis. Initial goals of therapy were to prevent symptoms of hyperglycemia and ketoacidosis. With the initiation of insulin therapy, hypoglycemia and the chronic complications of diabetes became apparent.

### Microvascular Complications

The DCCT was a pivotal study in understanding the importance of maintaining euglycemia, revealing that patients with T1D who received intensive insulin therapy had significantly fewer microvascular complications. Development or progression of retinopathy was reduced by 63%, and the need for laser therapy was reduced by 51%. The development of albuminuria (>300 mg/day) was reduced by 54% and clinical neuropathy by 60%. The population enrolled was relatively young at the beginning of the study (mean age 27 years) and did not show a statistically significant decline in macrovascular events. The EDIC trial was

an extension of the original DCCT cohort. After 17 years of follow-up from initial randomization, more than 90% of the patients were assessed for macrovascular disease. The EDIC trial found at 17-year follow-up that patients who had previously been treated with intensive insulin therapy had a significantly lower number of macrovascular events, including acute myocardial infarction and stroke. This instance was the first time a benefit in the reduction of macrovascular disease had been reported in patients with T1D as a result of intensive insulin therapy.

The reduction in microvascular complications has also been demonstrated for patients with T2D. Undoubtedly, diabetes (type 1 or type 2) greatly increases the risk for blindness, chronic kidney disease, neuropathy, cardiovascular disease, and stroke. The evidence is clear that these risks can be attenuated in adolescents and adults treated with intensive diabetes management. Merely treating to avoid symptoms of hyperglycemia is not acceptable. Data regarding the prevention of chronic complications of diabetes in younger children and infants with intensive glucose management are not available.

### Hypoglycemia

Hypoglycemia is a common complication of intensive diabetes management. In addition to the frequency of hypoglycemia, the severity of hypoglycemia should be assessed. Mild hypoglycemia is the result of the adrenergic response to low blood glucose levels. Severe hypoglycemia is defined as an episode requiring treatment. With severe hypoglycemia, the patient has neurologic symptoms, which can include confusion or loss of consciousness. The DCCT clearly showed that the incidence of severe hypoglycemia markedly increased with lowering of the HbA<sub>1c</sub> level (see Figure 241-1).

When a child experiences symptoms of hypoglycemia, the blood glucose level should be checked to document that the symptoms are caused by a low blood glucose level. Some symptoms of hypoglycemia are nonspecific, and unnecessary treatment should be avoided. If hypoglycemia is mild or moderate, generally 10 to 15 g of carbohydrate will correct the situation. The glucose level should be rechecked in 15 to 20 minutes to be certain the hypoglycemia has resolved. Glucose tablets and gels are available and easy to carry. Some form of carbohydrate should always be available to the patient for the treatment of hypoglycemia.

In an unconscious child, severe hypoglycemia may be treated with glucagon or intravenous glucose. Training on the proper use of glucagon should be provided to individuals caring for the child, such as parents, school nurses, older siblings, and others. Glucagon is reserved for patients with severe hypoglycemia who are not able to ingest carbohydrate. Glucagon effectively raises blood glucose by stimulating glucose release from the liver. However, this response is relatively short lived, and as soon as practical, the child should eat (although the nausea that frequently accompanies glucagon administration makes this requirement more complicated). After an episode of hypoglycemia is successfully treated, a cause of the hypoglycemia should be considered. If no cause is readily apparent, then an adjustment in the

insulin dose should be made the next day to avoid additional hypoglycemia. This advice is in contrast to monitoring glucose trends before making adjustments to prevent hyperglycemia. One episode of unexplained hypoglycemia should prompt an insulin adjustment.

Less tight glycemic control should be considered for patients with frequent severe hypoglycemia because of the possibility of long-term neurologic consequences. Children younger than 5 or 6 years of age at the time of diagnosis appear to be at particularly high risk for experiencing frequent hypoglycemia and cognitive impairment.

### Other Considerations

The successful management of diabetes is complex and requires a committed team of health care providers and significant social support for the child. Although the focus of treatment is centered on safely achieving glycemic goals in an attempt to avoid complications, these complications cannot be prevented in all patients. Screening for chronic complications must be performed to intervene early to reverse or slow disease progression. Screening for diabetic retinopathy is recommended for all individuals with diabetes. Developing retinopathy within the first 3 years of diagnosis is unusual for a child, especially if the child is younger than 10 years. Ophthalmologic evaluation for children with T1D should start at age 10 years in those who have had T1D between 3 and 5 years, with annual follow-up thereafter.

Diabetic nephropathy is a leading cause of chronic kidney disease and need for dialysis. Similar to retinopathy, diabetic nephropathy is uncommon in the young or newly diagnosed patient with T1D, and screening should start at age 10 years in children who have had T1D for at least 5 years. The ADA recommends screening with a random urine sample to determine the microalbumin-to-creatinine ratio. A ratio of 30 mg/g (albumin to creatinine) or greater is considered abnormal, and further testing may be indicated. Because other factors may contribute to albuminuria, including exercise, 2 to 3 abnormal determinations may need to be obtained to confirm the diagnosis. Treatment with an Angiotensin converting enzyme (ACE) inhibitor, titrated to normalization of albumin excretion, should be considered when elevated albumin-to-creatinine ratio is subsequently confirmed on two additional specimens from different days over at least 2 months. Girls should be counseled on the teratogenicity of ACE inhibitors. Screening for hypertension should be performed at each routine visit. Children found to have high-normal blood pressure or hypertension should have their blood pressure confirmed on a separate day, and if the blood pressure is consistently elevated to more than 90th percentile for age, height, and gender, ACE inhibitor therapy is the first-choice treatment.

Screening for dyslipidemia should be performed on children older than 2 years soon after diagnosis (after glucose control has been established) if there is a family history of hypercholesterolemia or a cardiovascular event before age 55 years, or if family history is unknown. If family history is not of concern, first lipid screening can be obtained at puberty ( $\geq 10$  years of age). For children diagnosed with diabetes at or after puberty, consider obtaining a fasting lipid profile soon

after the diagnosis (after glucose control has been established). If lipids are abnormal, annual monitoring is reasonable, with institution of lifestyle changes. If low-density lipoprotein cholesterol values are within the accepted risk levels ( $<100$  mg/dL), a lipid profile repeated every 5 years is acceptable.

Patients with T1D are at increased risk for developing other autoimmune disorders, including thyroid disease and celiac disease. Screening for thyroid disease should begin at or shortly after diagnosis by measurement of sensitive thyroid-stimulating hormone and performed annually thereafter. The ADA also recommends biochemical screening of children for celiac disease because patients with T1D are at higher risk for this disease, which can significantly affect the nutritional requirements of the child. Screening for celiac disease can be performed by measuring tissue transglutaminase antibodies. Normal total immunoglobulin A concentrations should also be documented. If unexplained hypoglycemia is occurring (especially with decreasing insulin requirements), evaluation for adrenal insufficiency should be undertaken.

### CONCLUSION

Although significant advances have been made in the types of insulin available and the tools used to monitor blood glucose concentrations, the ability to replicate the function of an intact pancreas is crude at best. Therefore, the child with diabetes requires a significant amount of effort on a daily basis. Providing adequate, individualized education and support for children with diabetes is imperative for successful treatment.

#### WHEN TO REFER

- All newly diagnosed children with T1D or T2D
- When a multidisciplinary diabetes program is needed and not available

#### WHEN TO ADMIT

- Considered for all patients with newly diagnosed T1D
- Diabetic ketoacidosis
- Considered for severe hypoglycemia or dehydration

## Chapter 242 DIAPER RASH

Daniel Krowchuk, MD

Diaper rash is the most common skin disorder of infancy. As many as 25% of infants and toddlers are affected; the peak incidence is between 9 and 12 months of age. Diaper rashes may be separated into 2 groups—those that primarily affect the diaper area and are related to wearing a diaper, and those that are associated with systemic disorders that may involve the perineum. The 2 most common forms of primary diaper dermatitis, irritant contact dermatitis (ICD) and candidiasis, will be discussed in detail here. The key features of other forms of primary diaper dermatitis and systemic disorders that may affect the diaper area will be summarized in Table 242-1 and Table 242-2.

### ETIOLOGY

Irritant contact dermatitis is responsible for most rashes in the diaper area. Several factors contribute, including excessive skin moisture, friction, and fecal enzymes. Excessive hydration makes the skin more susceptible to the effects of frictional forces, predisposing to the development of erosions; enhances skin permeability, permitting more rapid penetration of irritating substances; and promotes the growth of microorganisms. Feces contain proteases and lipases, both of which may act as skin irritants. These enzymes are activated at higher pH

levels, a condition that occurs when urea in urine is converted to ammonia. Not surprisingly, reduced frequency of diaper changing (fewer than 8 times per day) and diarrhea are associated with the development of ICD. Once the skin has been damaged by ICD or another process, infection with *Candida albicans* may occur. Candidiasis should be suspected when an apparent ICD does not respond to standard therapy or when a diaper rash appears during or shortly after antibiotic therapy. Ten days of oral amoxicillin therapy has been associated with a twofold increase in the recovery of *C. albicans* from the rectum and skin.

## HISTORY

Elements of the history that may be useful in evaluating diaper rash include the following:

- Duration of the eruption (ICD present for more than 72 hours often is secondarily infected with *C. albicans*)
- Associated symptoms (eg, diarrhea)
- Type of diaper used (disposable or cloth)
- Laundering method (if cloth diapers used)
- Frequency of diaper changing
- Medication use (eg, antibiotic therapy that predisposes to *C. albicans* infection or potent topical corticosteroid use that may contribute to granuloma gluteale infantum)
- Presence of rash elsewhere or systemic symptoms (which might indicate a systemic cause of the diaper rash)
- Family history (which might be helpful when considering psoriasis)

## PHYSICAL EXAMINATION

ICD appears on the convexities of the lower abdomen, perineum, buttocks, and proximal thighs with relative sparing of the creases (eg, inguinal folds). In mild cases,

**Figure 242-1** Irritant diaper dermatitis. Erythematous patches sparing the skin folds.

there is erythema, possibly with scaling, while more severely affected individuals exhibit superficial erosions (Figure 242-1). Infection with *C. albicans* typically produces “beefy”-red patches that involve the convexities and creases. Scaling, particularly at the periphery of patches, or satellite papules or pustules may be present (Figure 242-2). The physical findings associated with other causes of diaper rash are summarized in Table 242-1 and Table 242-2 and shown in the figures.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of common and less common forms of diaper rash occurring in infants and toddlers is presented in Table 242-1 and Table 242-2. A number of infections (herpes simplex virus infection, molluscum contagiosum, hand-foot-and-mouth disease) or infestations (scabies) may involve the diaper area, but lesions would also be expected elsewhere or systemic symptoms would normally be evident. Kawasaki disease may produce perineal erythema and desquamation during the first week of symptoms; in some patients, this may be the only rash. The eruption involves the convexities and creases with an appearance similar to that of toxin-mediated erythemas like scarlet fever. Bullae or erosions affecting the diaper area may result from bullous impetigo (Table 242-1), burns (including those from nonaccidental trauma), senna-containing laxatives (Table 242-2), or epidermolysis bullosa.

## LABORATORY FINDINGS

Laboratory studies are not needed in the evaluation of most diaper rashes. Tests that may be helpful include the following:

- Potassium hydroxide preparation to demonstrate the pseudohyphae and spores of candidiasis or the hyphae of tinea corporis (a fungal culture might be performed instead)
- Mineral oil preparation to confirm scabies infestation (mites, eggs, or fecal material might be observed)

**Figure 242-2** Erythematous patches that involve the creases and convexities are characteristic of candidal diaper dermatitis. Satellite lesions and scaling are present.

**Table 242-1** Other Common Forms of Diaper Rash

CONDITION	CAUSE	CLINICAL FEATURES	TREATMENT
Seborrheic dermatitis (Figure 242-3)	<ul style="list-style-type: none"> <li>• Cause unknown</li> <li>• Associated with sebaceous gland function</li> <li>• May represent an inflammatory response to yeasts of the genus <i>Malassezia</i></li> </ul>	<ul style="list-style-type: none"> <li>• Begins at 3–4 weeks of age and resolves by the end of the first year of life</li> <li>• Salmon-pink patches with greasy scale that involve the convexities and inguinal creases</li> <li>• Involvement of the scalp, face, retroauricular creases, umbilicus, or chest may be present</li> </ul>	<ul style="list-style-type: none"> <li>• Skin: Topical low-potency corticosteroid or antifungal preparation (eg, nystatin, clotrimazole)</li> <li>• Scalp: Oil massage and brushing or antiseborrheic shampoo (containing, eg, pyrithione zinc or selenium sulfide)</li> </ul>
Bullous impetigo (Figure 242-4)	<ul style="list-style-type: none"> <li>• Infection with <i>Staphylococcus aureus</i> that elaborates epidermolytic toxin</li> </ul>	<ul style="list-style-type: none"> <li>• Flaccid blisters filled with clear or purulent fluid</li> <li>• Blisters rupture rapidly, leaving round or oval crusted erosions with a rim of scale</li> </ul>	<ul style="list-style-type: none"> <li>• Oral antistaphylococcal antibiotic (the agent selected depends on local antibiotic resistance patterns)</li> </ul>
Folliculitis (Figure 242-5)	<ul style="list-style-type: none"> <li>• Infection of hair follicles with <i>S aureus</i></li> </ul>	<ul style="list-style-type: none"> <li>• Pustules with surrounding erythema that are centered around hair follicles</li> </ul>	<ul style="list-style-type: none"> <li>• Many lesions: Oral antistaphylococcal antibiotic (the agent selected depends on local antibiotic resistance patterns)</li> <li>• Few lesions: Topical antibiotic (eg, mupirocin, clindamycin, retapamulin)</li> <li>• Bleach baths may be useful for patients with persistent/recurrent infections</li> </ul>
Intertrigo (Figure 242-6)	<ul style="list-style-type: none"> <li>• Rubbing of apposed skin surfaces complicated by heat and moisture</li> </ul>	<ul style="list-style-type: none"> <li>• Erythema and superficial erosions located in the inguinal creases</li> <li>• May become secondarily infected with <i>Candida</i> species or <i>Streptococcus pyogenes</i></li> </ul>	<ul style="list-style-type: none"> <li>• Absorbent powder (to reduce moisture and friction)</li> <li>• Antifungal preparation (if candidal infection) or antibiotic (if streptococcal infection)</li> </ul>
Jacquet's erosive diaper dermatitis (Figure 242-7)	<ul style="list-style-type: none"> <li>• Multiple factors, including moisture, friction, enzymes in stool</li> <li>• Considered a variant of irritant dermatitis</li> </ul>	<ul style="list-style-type: none"> <li>• Well-defined shallow ulcers or ulcerated nodules</li> </ul>	<ul style="list-style-type: none"> <li>• Topical low-potency corticosteroid twice daily and barrier preparation at all diaper changes</li> </ul>

- Bacterial culture for *S aureus*
- Serum zinc concentration if suspicion exists for acrodermatitis enteropathica (other testing will be required to identify nutritional disorders that produce similar physical findings, such as essential fatty acid deficiency or kwashiorkor)
- Skin biopsy if concern exists for Langerhans cell histiocytosis
- Osseous survey if nonaccidental trauma is suspected in a child younger than 2 years of age

## MANAGEMENT

A key to managing ICD is to reduce moisture through frequent diaper changes (every 3 to 4 hours and after soiling). Although it would be helpful to allow diaper-free periods, this may not be feasible. When the perineum is soiled, bathing or cleansing with a disposable wipe or a washcloth and water is indicated. Wipes are convenient to use. Current varieties contain water,

an emollient, and surfactants; they have been found to be safe for use on normal infant skin and skin that has been damaged. Choosing a product that is fragrance free may help avoid sensitization. Preservatives occasionally may induce allergic contact dermatitis, but can be more difficult to avoid. After cleansing, the skin should be allowed to dry before diapering. Applying a barrier preparation at each diaper change will protect the skin from moisture. Zinc oxide paste and petrolatum are commonly used and effective. Zinc oxide adheres well to the skin and, as a result, provides greater protection. It may also adhere to the diaper; if this becomes a problem, the zinc oxide may be covered with a thin layer of petrolatum. Both zinc oxide and petrolatum are available individually and are the active ingredients in many combination products, along with beeswax, lanolin, mineral oil, olive oil, and other agents.

If ICD is moderate or severe, a low-potency topical corticosteroid (eg, hydrocortisone 1% or 2.5%) may be applied twice daily. The use of more potent preparations

**Figure 242-3** Salmon-pink patches with greasy scale involve the creases and convexities in seborrheic dermatitis.

**Figure 242-6** Intertrigo, shown here involving the neck, produces superficial erosions in areas where moist skin surfaces are in apposition.

**Figure 242-4** Flaccid bullae that rupture easily leaving round, crusted erosions occur in bullous impetigo.

**Figure 242-7** Jacquet's erosive diaper dermatitis. Well-defined shallow ulcers and ulcerated nodules.

**Figure 242-5** Folliculitis produces pustules and erythematous papules that are centered around hair follicles.

should be avoided. Recall that the perineum is occluded by the diaper and that the epidermis is thin—factors that enhance the absorption of topical steroids and increase the likelihood of adverse effects locally (eg, atrophy, striae) and systemically (eg, Cushing syndrome).

If the physical examination suggests candidiasis (or if ICD has been present for more than 72 hours and is not improving with standard treatment), nystatin or an imidazole (eg, clotrimazole, miconazole, ketoconazole, etc) should be used. Imidazoles may be a more convenient choice in view of twice-daily dosing. If both a topical corticosteroid and an imidazole are to be used, an alternating application schedule may be selected. A barrier preparation should be applied at all diaper changes where the topical corticosteroid or antifungal is not being used. In infants with skin of

color, the inflammation caused by ICD or other forms of diaper dermatitis may cause hypopigmentation. Parents should be advised that this is temporary but may require several months to resolve.

## PREVENTION

Gregory Liptak, MD, the previous author of this chapter, wrote in the first edition, “If no diapers existed, no diaper rashes would occur.” Because going diaper

free is unacceptable, parents must choose between disposable and cloth diapers. Some issues that influence this decision include effectiveness, prevention of diaper dermatitis, cost, and ecologic effect. Studies conducted during the 1980s demonstrated that the use of disposable diapers containing absorbent gelling material (AGM, the substance that stores liquid in the core of the diaper keeping it away from the skin) was associated with reductions in the frequency and severity of diaper dermatitis when compared with the use of either

**Figure 242-8** Psoriasis in the diaper area produces erythematous patches or plaques. Unlike lesions elsewhere, scale may be absent.

**Figure 242-9** Acrodermatitis enteropathica causes erythematous patches in the diaper area and around the mouth.

cloth or cellulose-only diapers (ie, disposable diapers without AGM). However, there are no published data comparing disposable diapers and the current generation of cloth diapers. The increasing popularity of cloth diapers likely reflects, in part, satisfaction with their performance. Depending on the brand, these diapers use a cloth insert (to enhance absorbency) and a breathable waterproof cover to contain moisture. Some varieties also use a flushable inner liner to contain fecal material, eliminating the need to rinse the diaper before placing it in the diaper pail.

Disposable diapers are convenient, but comparatively more expensive than cloth varieties. A *Consumer Reports* Diaper Buying Guide (updated November 2012) estimates that a family might spend \$2,500 or

**Figure 242-10** Erythematous papules of Langerhans cell histiocytosis.

**Figure 242-11** Condylomata lata, flat-topped papules and plaques, occur in the diaper area in congenital syphilis.

more on disposable diapers by the time a child is toilet trained. If a biodegradable variety is used, the cost may be \$3,500. Cloth diapers are less expensive, especially if the family does the laundering (ie, does not use a diaper service). In addition, cloth diapers could be used for more than a single baby.

The environmental effect of disposable diapers is an issue of concern. Past estimates suggested that non-biodegradable disposable diapers made up 1% to 2% of landfills. However, washing cloth diapers requires water and energy, along with detergent and human effort. These factors must be considered in weighing the overall environmental effect of these products. In an analysis by the Environmental Agency of the United Kingdom, a child using 2006-type disposable diapers for 2½ years contributed a global warming effect of approximately 550 kg of carbon dioxide equivalents.

Reusable diaper use resulted in 570 kg of carbon dioxide equivalents (assuming average washer and dryer use). The latter amount could be reduced by 40% by washing diapers in fuller loads, line drying them all the time, and using the diapers for a second child.

Beyond appropriate diapering, measures that prevent diaper dermatitis include frequent diaper changes, appropriate cleansing promptly after soiling, and the application of a barrier preparation after cleansing the diaper area (particularly for infants who experience recurrent episodes of diaper dermatitis).

### WHEN TO REFER

- If an infant fails to respond to appropriate therapy (to consider alternate diagnoses and possibly perform skin biopsy) or if nonaccidental trauma is suspected.
- If Langerhans cell histiocytosis is considered, refer to a pediatric dermatologist or pediatric oncologist.
- Consultation with a pediatric infectious diseases specialist is warranted if an infant is suspected of having congenital syphilis.

## Chapter 243

# DISORDERS OF SEX DEVELOPMENT

Lindsey Loomba-Albrecht, MD; Dennis M. Styne, MD

### EPIDEMIOLOGY

Patients with ambiguous genitalia have *disorders of sex development* (DSD), previously termed *intersex conditions*. These are congenital conditions in which

development of chromosomal, gonadal, or anatomic sex is atypical. Physical findings in patients with DSD may range from an apparently normal phenotype to complete ambiguity. Disorders of sex development is considered an endocrine emergency because many common forms of DSD (ie, congenital adrenal hyperplasia [CAH]) are associated with life-threatening electrolyte abnormalities, hypotension, and shock. In addition to the potential medical emergency, the psychological stress to the family cannot be overstated. Gender assignment in patients with genital ambiguity should be made only after careful investigation by a multidisciplinary team; increasingly, surgical decisions are delayed until the child is able to participate in the decision-making process.

### NORMAL HUMAN SEXUAL DIFFERENTIATION

Phenotypic sex results from the culmination of many specific genetic and hormonal processes. Humans possess 23 pairs of chromosomes (22 pairs of autosomes and 1 pair of sex chromosomes), with females possessing 2 X chromosomes and males possessing 1 X and 1 Y chromosome. Early in gestation, the fetus has a bipotential gonad that can develop into either ovaries or testes. Genes on the sex chromosomes, as well as on the autosomes, influence formation of this bipotential gonad into either ovaries or testes. Additionally, both the Wolffian and Müllerian ducts are present early in gestation; these have the potential to develop into either male or female nongonadal reproductive structures, respectively.

#### Male Sexual Differentiation

The presence of a specific gene on the Y chromosome, the sex-determining region Y (*SRY*) gene, is the initial trigger for testicular development and, eventually, the male phenotype. When the *SRY* gene is present, the bipotential gonad begins to differentiate into a testis at day 43 to 50 of gestation. Soon after, the testes begin to produce testosterone from the Leydig cells and anti-Müllerian hormone (AMH) or Müllerian-inhibiting substance from the Sertoli cells. The anti-Müllerian hormone acts locally to repress ipsilateral development of the Müllerian ducts through apoptosis. Because AMH is produced through early childhood, it can be used as a marker for Sertoli cell presence and function until 8 to 10 years of age. The Wolffian ducts differentiate in the male and, with high local concentrations of testosterone from the ipsilateral testes, ultimately form the vas deferens, epididymis, seminal vesicles, and ejaculatory ducts.

Testosterone secretion early in gestation (during the critical period of sex determination) is stimulated by placental human chorionic gonadotropin (hCG); later the stimulus for testosterone secretion is luteinizing hormone (LH) released from the fetal pituitary. Testosterone is locally metabolized by the enzyme 5 $\alpha$ -reductase into dihydrotestosterone (DHT), which is responsible for masculinization of the external genitalia in the male. Thus, the development of a male phenotype begins with specific genetic signals that lead to gonadal (testis) formation; the gonads then produce androgenic hormones that allow for masculinization

of the genitalia. A critical window exists in which testosterone secretion must occur to lead to the normal male phenotype. If fusion of the labioscrotal folds does not occur by week 14 of gestation, then fusion will not occur even if high levels of androgen are present later. After this time, the phallus enlarges and the testes descend into the scrotum, but most male differentiation already occurred. A female with excessive androgen exposure from early gestation (eg, virilizing CAH) will have some degree of fusion of the labia; virilizing CAH is incompatible with a normal female unfused vaginal opening.

### Female Sexual Differentiation

Without the *SRY* gene, the bipotential gonad will develop into an ovary beginning between days 77 and 84 of gestation. Thus, the default pathway in gonadal development is said to be female, although more recently, other genes such as *Wnt4* have been identified that play a role in development of the ovary. Without the production of AMH, the Müllerian ducts develop into the fallopian tubes, uterus, and upper one-third of the vagina. The developing ovaries do not secrete hormones necessary for female sexual differentiation. Essentially, the absence of androgenic hormones allows the typical female external genitalia to develop.

In addition to the *SRY* gene, multiple other genes play a role in human sexual differentiation. Most of these genes act downstream of the *SRY* gene to further influence testicular or ovarian differentiation. Mutations in these genes, such as *WT1*, *SF1*, and *SOX9*, are often associated with additional physical findings in the infant or later in childhood or adolescence.

### DEFINITIONS

Recently, the nomenclature used to describe atypical sexual differentiation changed, largely the result of concern that the terminology was pejorative to children and confusing to medical practitioners. Historically, the term *male pseudohermaphrodite* was used to describe the child with incompletely masculinized external genitalia possessing XY chromosomes and a typical number of autosomes (46,XY karyotype). Incomplete masculinization of a fetus with testes may result from decreased synthesis or secretion of testosterone or DHT, peripheral tissue resistance to

androgen action, or defective production or action of AMH. These conditions, as well conditions in which the testes fail to normally develop, are now denoted as 46,XY DSD. The term *female pseudohermaphrodite* was commonly used to describe a child with a 46,XX karyotype and with masculinized external genitalia. This circumstance may result from abnormally high levels of androgen from either a fetal or exogenous source. Currently, these disorders, as well as disorders of ovarian development, are denoted as 46,XX DSD.

*Sex chromosome DSD* now describes sex chromosome abnormalities that affect gonadal development. These conditions may or may not involve genital ambiguity. In very rare cases, a child may have both ovarian and testicular tissue. These children called *true hermaphrodites* in the past, but may now be considered to have *ovotesticular DSD*.

## DISORDERS OF SEXUAL DEVELOPMENT

### 46,XX Disorders of Sexual Development

Virilization of a female fetus results from excess androgen exposure from either a fetal or maternal source. Timing is important; if the female is exposed to elevated androgen levels after week 8 of gestation, but before week 14, then the vaginal opening may fuse posteriorly and seem slit-like. Females with CAH, for example, will have posterior fusion of the labia and some degree of clitoromegaly given their high circulating androgen levels between weeks 8 and 14 of gestation. Exposure to androgen following weeks 12 to 14 of gestation (eg, exogenous administration to the mother) will result in clitoromegaly without fusion of the labioscrotal folds.

### Fetal Sources of Androgen Excess

**CONGENITAL ADRENAL HYPERPLASIA.** Overproduction of adrenal androgens by the female fetus may occur in virilizing CAH, a group of disorders in which a biochemical defect in cortisol synthesis leads to hyperplasia of the adrenal gland resulting from compensatory elevation in adrenocorticotrophic hormone (ACTH). These disorders are inherited in an autosomal recessive manner. The degree and timing of virilization, as well as the presence or absence of salt wasting, depend on the specific genetic lesion (Table 243-1).

**Table 243-1** Differential Diagnosis of Adrenal Enzyme Defects

DEFICIENCY	NEWBORN PHENOTYPE	POSTNATAL VIRILIZATION	OTHER
StAR (also called <i>lipoid congenital adrenal hyperplasia</i> )	Infantile female	—	Salt loss
3 $\beta$ -Hydroxylase	Ambiguous in XY and XX	+	Salt loss
17 $\alpha$ -Hydroxylase (P450c17)	Infantile female	—	Delayed puberty
11 $\beta$ -Hydroxylase (P450c11 $\beta$ )	Male in XY, ambiguous in XX	+	Hypertension
21-Hydroxylase (P450c21)	Male in XY, ambiguous in XX	+	Salt loss
18-Hydroxylase (P450c11B2)	Normal	—	Salt loss

StAR, steroidogenic acute regulatory protein.

From Styne D. *Pediatric Endocrinology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2004. Reprinted by permission.

Roughly 90% of classic CAH cases are caused by 21-hydroxylase deficiency, which occurs in 1 in 15,000 live births. P450c21 hydroxylase converts 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol; a deficiency in this enzyme leads to extreme elevation in 17-OHP levels, making serum levels of 17-OHP a useful diagnostic test. Defects in 21-hydroxylase will lead to low aldosterone and cause renal salt wasting and potassium retention in approximately 50% of children. In its most serious form, cortisol and aldosterone deficiency are severe enough to result in hyponatremia, hyperkalemia, dehydration, hypotension, shock, or death. Male infants die more frequently than female infants because of the lack of suspicion of the condition as a result of their visibly normal phenotype at birth, whereas female infants with virilization are usually evaluated quickly. Newborn screening should eliminate this gender discrepancy in timing of diagnosis.

Late-onset, or nonclassic, 21-hydroxylase deficiency usually occurs in childhood or the teenage years with excessive or premature acne and sexual hair. It is a milder, non-life-threatening form of CAH that does not cause genital ambiguity. It may be associated with increased growth, bone age advancement, and irregular menses, and is frequently evaluated in the workup of precocious puberty.

Defects in 11 $\beta$ -hydroxylation are rarer than defects in 21-hydroxylation, occurring in roughly 1 in 100,000 white births and more frequently in those of Middle Eastern descent. P450c11 hydroxylase deficiency typically results in hypertension in either gender as a result of elevated levels of 11-deoxycorticosterone and virilization of the female fetus as a result of increased adrenal androgen production. Diagnosis is usually made after the discovery of elevated levels of 11-deoxycortisol (compound S).

3 $\beta$ -Hydroxysteroid-dehydrogenase deficiency causes mineralocorticoid, glucocorticoid, and sex-steroid deficiency. Genetic females may be phenotypically normal or have varying levels of clitoromegaly or labial fusion. Virilization occurs in genetic females because of increased levels of dehydroepiandrosterone (DHEA) (and its sulfate DHEA-S). Additionally, peripheral conversion of DHEA to testosterone may cause virilization in females. 3 $\beta$ -Hydroxysteroid-dehydrogenase deficiency may be a cause of late-onset CAH. Salt loss, as a result of aldosterone deficiency, occurs to varying degrees. Genetic male fetuses may have genital ambiguity as well.

**AROMATASE DEFICIENCY.** In rare cases, deficiency in the enzyme aromatase caused by mutations in the *CYP19* gene may lead to virilization of the female fetus and often of the mother during pregnancy. Aromatase catalyzes the conversion of androgen to estradiol; a deficiency in this enzyme leads to elevated levels of androstenedione and testosterone and low levels of estrogens in these patients. At puberty, females often undergo progressive virilization and do not develop female secondary sexual characteristics. In addition, they have osteopenia and delayed bone age (given the estrogen deficiency) and may have ovarian cysts. A male with aromatase deficiency will be tall and have delayed bone age and osteoporosis caused by estrogen deficiency.

### Maternal or Exogenous Sources of Elevated Androgen Levels

Maternal use of androgenic steroids such as danazol or certain progesterone compounds during pregnancy may lead to virilization of the female fetus. Again, the time frame is important in the outcome, given that exposure to these compounds during weeks 8 to 14 of gestation may lead to significant ambiguity, whereas later exposure may result only in enlarged clitoral size. In rare instances, maternal CAH or a virilizing maternal tumor of ovarian or adrenal origin may lead to masculinization of the fetus. Luteomas of pregnancy are also reported to cause genital ambiguity in the newborn, although they more commonly result only in maternal virilization.

### 46,XY Disorders of Sexual Development Luteinizing Hormone-Receptor Defects

Testosterone secretion is controlled by hCG early in gestation and LH from the fetal pituitary later in gestation. Failure of hCG or LH to stimulate testosterone production at the critical times because of mutations in the LH/hCG receptor will result in incomplete masculinization of a male fetus. This failure may result in Leydig cell agenesis or hypoplasia. Stimulation testing with hCG will result in little or no rise in androgen levels. Basal and stimulated LH levels are typically elevated.

### Androgen Biosynthesis Defects

Enzyme defects in the pathways of testosterone biosynthesis may result in incomplete virilization of the male fetus; some of the defects additionally affect synthesis of corticosteroids and are thus forms of CAH.

The initial conversion of cholesterol to pregnenolone requires the enzyme P450scc (side chain cleavage), as well as the steroidogenic acute regulatory protein, which transports cholesterol to the inner mitochondrial membrane where P450scc is located. Patients with steroidogenic acute regulatory protein or P450scc enzyme deficiencies have lipid-laden adrenal glands, adrenal insufficiency, and sexual infantilism in males as a result of low testosterone levels.

3 $\beta$ -Hydroxysteroid dehydrogenase deficiency may result in mineralocorticoid, glucocorticoid, and sex-steroid deficiencies. Affected males may be incompletely masculinized at birth and often experience salt loss or adrenal crisis in infancy. They may experience gynecomastia around the time of puberty. The enzyme substrates, such as DHEA and pregnenolone, are elevated.

17-Hydroxylase deficiency caused by a defect in the *CPY17* gene results in deficiencies in cortisol and testosterone and thus can result in an incompletely masculinized 46,XY fetus. An excess of the mineralocorticoid deoxycorticosterone leads to hypertension in both sexes (caused by increased salt and water reabsorption), as well as hypokalemia and suppression of aldosterone production. Females with 17-hydroxylase deficiency are phenotypically normal at birth, but will not progress through pubertal changes. In some female patients, primary amenorrhea is the presenting feature.

Enzyme defects affecting testosterone biosynthesis without affecting corticosteroid production also occur. In a male fetus, 17,20 lyase (also called 17,20 desmolase) deficiency and 17 $\beta$ -hydroxysteroid dehydrogenase-3 deficiency will lead to an incompletely masculinized phenotype without any abnormalities related to mineralocorticoid or glucocorticoid effects. Virilization may occur at puberty in either condition. Gynecomastia may occur at puberty in those affected with 17,20 lyase deficiency.

### Defects in Androgen Action

The syndrome of complete androgen resistance (complete androgen insensitivity syndrome) results from a defect in the androgen receptor. Affected individuals are phenotypic females with a 46,XY karyotype and bilateral testes that secrete elevated levels of testosterone. The external genitalia are phenotypically female given the inability of the tissue to respond to dihydrotestosterone. Müllerian structures such as the cervix and uterus are absent or hypoplastic because production of AMH by the fetal Sertoli cells is normal, and thus the vagina ends in a blind pouch. At puberty, LH increases and leads to elevations in testosterone, some of which is converted peripherally to estrogens. This circumstance leads to the development of female secondary sexual characteristics. Pubic and axillary hair is sparse, if present at all, and menarche cannot occur. Diagnosis often follows a workup for primary amenorrhea and is suggested by ultrasound findings (showing absence of the corpus and cervix and the presence of testes) and elevated levels of testosterone. Removal of the testicular tissue is indicated, given the increased risk for neoplasm after puberty; however, the timing of removal is controversial. After the testes are removed, estrogen replacement is provided.

Incomplete forms of androgen resistance, also caused by mutations in the androgen receptor, have great phenotypic variability. External genitalia may range in appearance from completely ambiguous to mildly hypoplastic male genitalia with a small, but normally formed, phallus. Hypoplastic Wolffian duct structures are typically present, and Müllerian derivatives are absent because of production of AMH. At puberty, virilization is usually incomplete, and gynecomastia often becomes apparent. Axillary and pubic hair is normal in amount and distribution.

### 5 $\alpha$ -Reductase-2 Deficiency

Mutations in the *SRD5A2* gene coding for 5 $\alpha$ -reductase-2, an enzyme that converts testosterone to dihydrotestosterone, leads to DHT deficiency. At birth, affected males may have ambiguous genitalia or be phenotypically female as a result of decreased conversion of testosterone to DHT in the sexual skin during the critical times of male genital development. These patients have well-developed Wolffian ducts (because these structures are testosterone and not DHT responsive) and absent Müllerian structures (given that AMH is produced from the normal testes). During puberty, virilization occurs with growth of the phallus and testes, likely secondary to expression of a different form of the 5 $\alpha$ -reductase enzyme (type 1) in the liver and other tissues at that time with subsequent increases in

circulating DHT levels. Secondary sexual characteristics, such as increased muscle mass and voice deepening, occur. Laboratory testing reveals abnormally high testosterone/DHT ratios with normal to elevated testosterone and low to undetectable DHT. Confirmatory testing with mutation analysis of the 5 $\alpha$ -reductase-2 gene can be performed, but is not yet available commercially. Given the phenotypic appearance at birth, many affected male children with 5 $\alpha$ -reductase deficiency are raised as female. Following the physical changes that occur around the time of puberty, some children may adopt a male gender role in adolescence or early adulthood.

### Disorders of Gonadal Differentiation (Sex Chromosome Disorders of Sexual Development)

#### Klinefelter Syndrome

The most common form of primary hypogonadism in males is Klinefelter syndrome (47,XXY karyotype), with an incidence of 1 in 1,000 males. Before puberty, children may have decreased upper segment to lower segment ratios, small testes, an increased incidence of developmental delay (mainly in the areas of speech and language), and behavioral problems. Males are taller than expected from 5 to 6 years of age onward.

Onset of puberty is not usually delayed because Leydig cell function is characteristically less affected than seminiferous tubule function, and testosterone is often adequate to stimulate pubertal development. Serum gonadotropin levels rise after the onset of puberty as the testes become firm and rarely grow larger than 3.5 cm in diameter. After the onset of puberty, histologic changes of seminiferous tubule hyalinization and fibrosis, adenomatous changes of the Leydig cells, and impaired spermatogenesis occur. Gynecomastia is common (and later the risk for breast cancer is increased), and variable degrees of male secondary sexual development are found.

#### Turner Syndrome (Syndrome of Gonadal Dysgenesis)

Turner syndrome (45,X karyotype) is associated with a lack of secondary sexual development at the time of puberty, short stature, and a characteristic female phenotype that often includes webbing of the neck. It occurs in 1 in 2,500 live-born female infants and a far greater percentage of conceived pregnancies, given that roughly 15% of first-trimester spontaneous abortions have a 45,X karyotype. Cardiovascular anomalies are present in approximately 75% of women with Turner syndrome and include coarctation of the aorta in 12% and aortic valve abnormalities in 20%. The risk for aortic dissection is also greatly increased. However, in some cases, short stature may be the sole phenotypic manifestation of the syndrome. Classic manifestations of Turner syndrome are linked to the absence of the short stature homeobox (*SHOX*) gene on the X chromosome.

Children have streak gonads consisting of fibrous tissue without germ cells. Pubic hair may appear late and is usually sparse in distribution; adrenarche progresses in Turner syndrome even in the absence of

gonadarche. Serum gonadotropin concentrations in Turner syndrome are extremely high between birth and 4 years of age. They decrease toward the normal range in prepubertal children and then rise again dramatically after 10 years of age. Because of decreased ovarian secretion of estrogens, puberty does not usually begin spontaneously. Children have no pubertal growth spurt and reach a mean final height of 143 cm. Growth hormone function is usually normal in Turner syndrome, although growth hormone treatment increases growth rate and adult stature. Estrogen treatment is also offered in adolescence in these children to allow feminization. Health supervision guidelines should be followed to ensure comprehensive care for patients with Turner syndrome.

Various mosaic forms of Turner syndrome have been identified, with karyotypes such as 45,X/46,XX or 45,X/46,XY. These children may have any phenotype varying from normal female to normal male to manifestations of many of the features of Turner syndrome. Some have apparently normal gonadal function; others have an abnormality of 1 X chromosome, such as a ring X, which may be associated with severe intellectual disability and a variety of congenital malformations.

#### Other Disorders of Gonadal Development

Additional disorders of testicular development may be caused by complete XY gonadal dysgenesis (Swyer syndrome), partial gonadal dysgenesis, or gonadal regression. In these cases, *gonadal dysgenesis* is descriptive and bears no etiologic relationship to the *syndrome of gonadal dysgenesis* or Turner syndrome. In complete gonadal dysgenesis, 46,XY individuals fail to develop normal testes and instead have gonadal streaks, Müllerian duct development and Wolffian duct regression, and female external genitalia. Fifteen percent to 20% of these cases are caused by mutations in the *SRY* gene. Partial gonadal dysgenesis in 46,XY individuals leads to a variable amount of testosterone and AMH production; thus, it is usually associated with ambiguous genitalia and partial development of both the Wolffian and Müllerian ducts. In gonadal regression or vanishing testes syndrome, the testes are lost after the external genitalia and internal structures form. Thus, these 46,XY individuals will be phenotypically male except for absence of both testes. Given this circumstance, anorchia must be considered in all phenotypic male children with bilaterally nonpalpable testes.

Gonadal dysgenesis may occur in children with a 46,XX karyotype who may have streak gonads and failure to develop secondary sexual characteristics at the time of puberty, but none of the other characteristics of Turner syndrome. In addition to gonadal dysgenesis, genetic abnormalities such as translocation of the *SRY* gene can result in a 46,XX genotypic child developing testicular instead of ovarian tissue; these children may phenotypically resemble Klinefelter syndrome.

#### Ovotesticular Disorders of Sexual Development

Children with ovotesticular DSD have both ovarian and testicular tissue present. Most children have a 46,XX phenotype, and the remainder have a 46,XY

karyotype or 46,XX/46,XY chimerism. Great phenotypic variability exists in both the internal and external genitalia in these children. Although ovotesticular DSD should be considered in all children with DSD, a 46,XX/46,XY karyotype or a bilobate gonad in the inguinal region or labioscrotal folds should raise suspicion for the diagnosis.

### EVALUATION AND DIAGNOSIS

Infants with indeterminate gender, as well as some infants with relatively subtle genital findings, should be evaluated for a disorder of sexual differentiation. (Figure 243-1 and Figure 243-2 contain diagnostic algorithms.) In males, even very mild hypospadias can be considered to represent incomplete masculinization, although most uncomplicated cases do not need diagnostic evaluation. More severe degrees of hypospadias, especially when a testis is not palpable, should awaken concern for an identifiable abnormality. Thus, in an apparently phenotypic female, mild clitoromegaly may represent severe undervirilization in a genetic male who has undescended testes or, conversely, masculinization of a female fetus.

Specific recommendations exist for which genital findings should elicit concern for a sexual development disorder. In an apparent male born at term, bilateral nonpalpable testes, micropenis, perineal hypospadias, or a single undescended testis with hypospadias of any degree should be further evaluated. Because the testes do not normally descend until roughly 34 weeks of gestation, significantly preterm males with nonpalpable testes alone do not necessarily require evaluation. In an apparent female, clitoral hypertrophy of any degree, posterior labial fusion (but not just labial adhesions), or an inguinal or labial mass should alert the physician to a possibility of a sexual differentiation disorder. Of course, all infants with truly ambiguous genitalia and thus indeterminate gender also require evaluation. In addition, if a family history of DSD is present, or if discordance exists between the apparent gender of the infant and a previously obtained prenatal karyotype, then an evaluation should ensue.

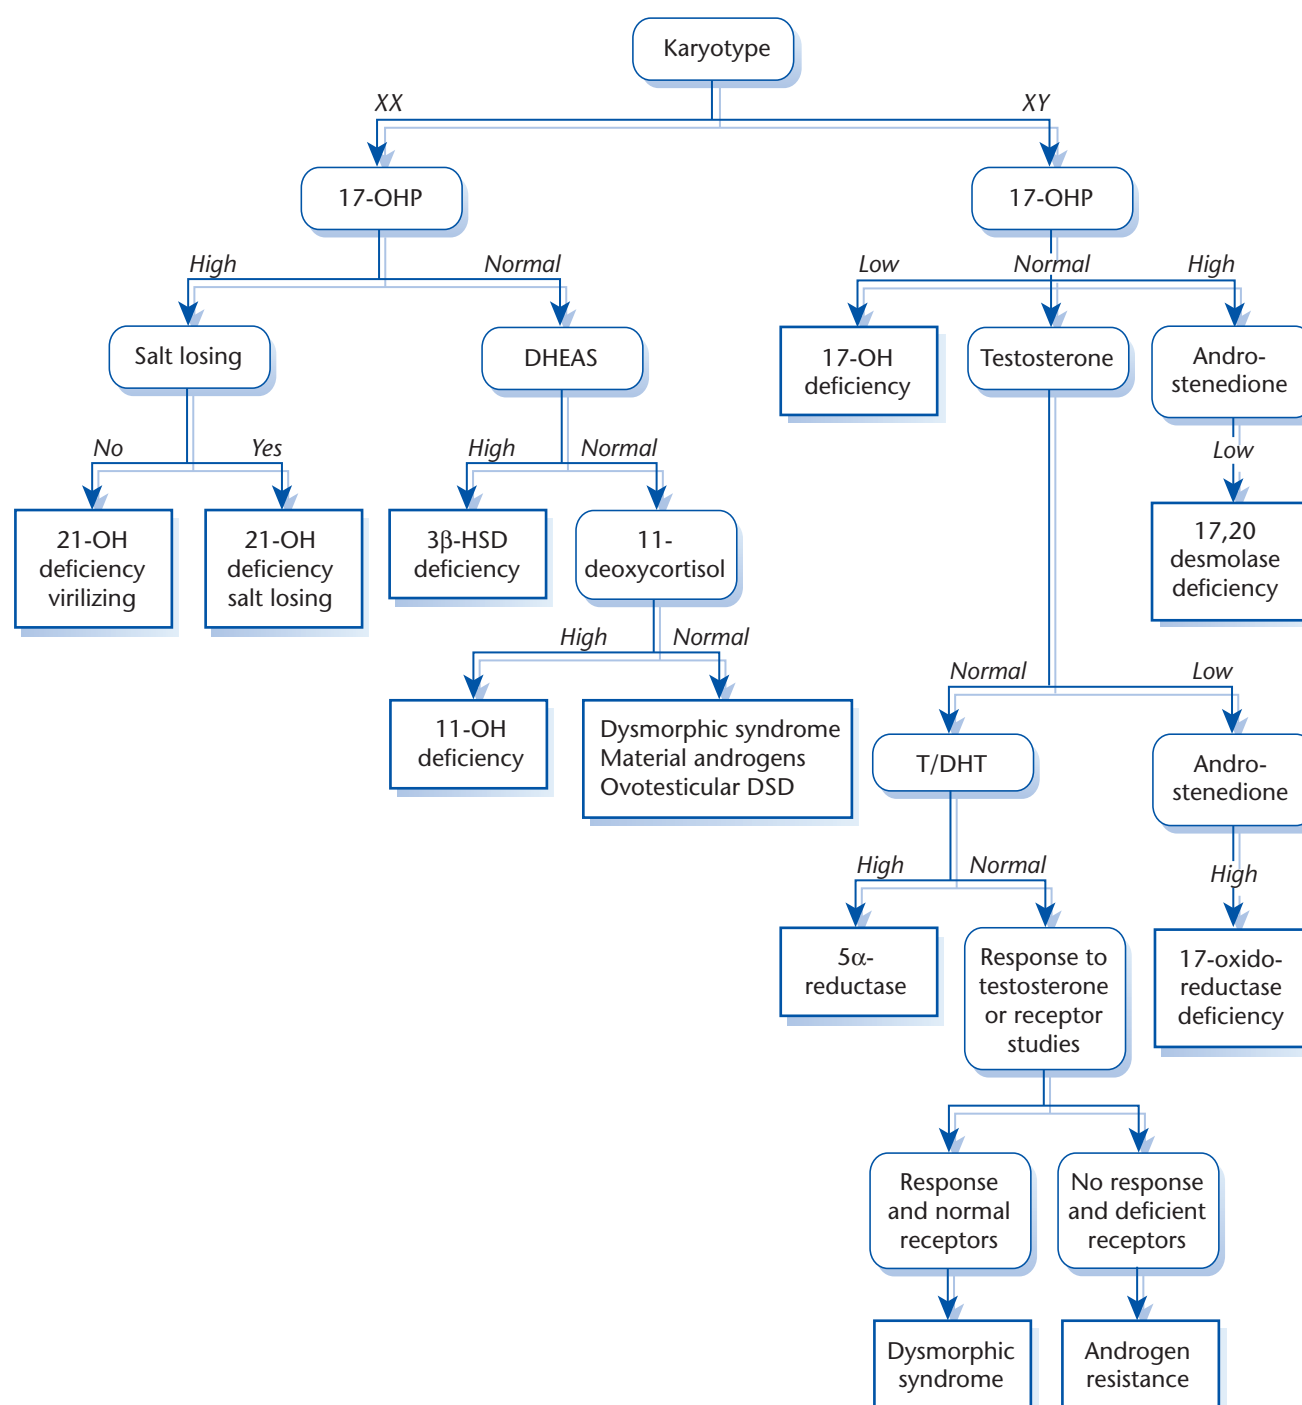

#### History

The evaluation of an infant with a DSD must include a detailed obstetric and family history. The child's mother should be asked about medication use and symptoms of virilization during pregnancy, which may occur in the case of aromatase deficiency or with androgen-secreting maternal ovarian or adrenal tumors. The family history should elicit a history of genital abnormalities, consanguinity, unexplained neonatal deaths especially in apparently normal phenotypic males (because males with CAH will not have the clue of genital ambiguity to raise suspicion for the possibility of adrenal crisis), infertility, and disorders of puberty. Many of the conditions associated with ambiguous genitalia are sporadic or inherited in an autosomal recessive manner.

#### Physical Examination

The initial physical examination should begin with an assessment of the general health of the child and an evaluation for malformations or dysmorphic features.

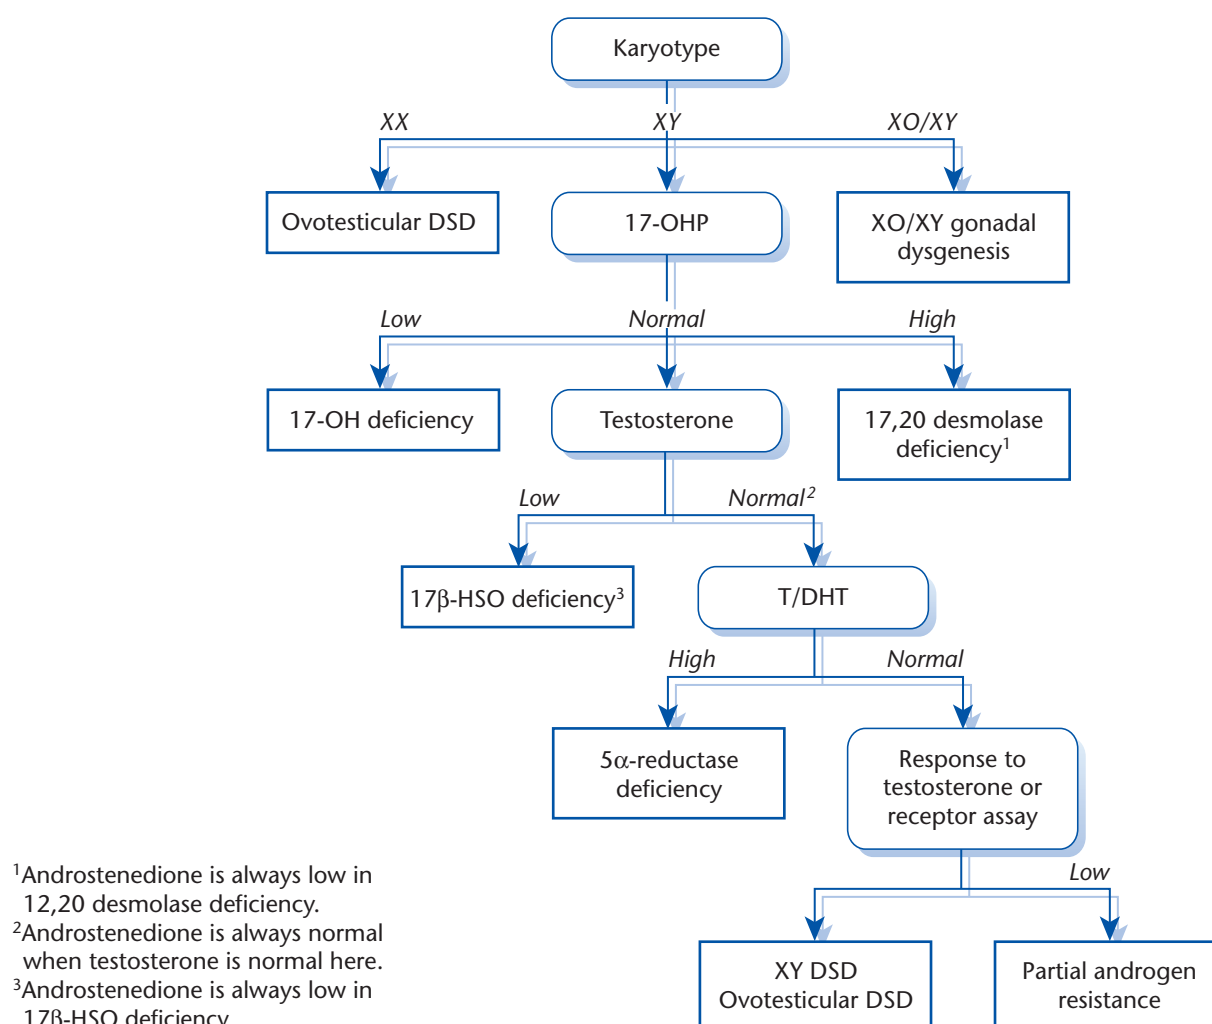

**Figure 243-1** Diagnostic algorithm for a child with ambiguous genitalia without palpable gonads is presented for information only. This complex clinical situation requires the assistance of a pediatric endocrinologist for ultimate diagnosis. *DHEAS*, dehydroepiandrosterone sulfate; *DSD*, disorders of sex development; *T/DHT*, testosterone/dihydrotestosterone. (From Styne D. *Pediatric Endocrinology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2004. Reprinted by permission.)

Unstable vital signs or hypoglycemia with no apparent cause should raise concern for cortisol deficiency associated with CAH. Typically, the onset of shock in children with CAH does not develop until day 4 to 5 of life, and normal electrolyte values in the few days after birth do not exclude salt loss. Children with ambiguous

genitalia may actually benefit from earlier diagnosis of salt loss and signs of cortisol deficiency than phenotypically normal children. Increased skin pigmentation caused by elevated levels of ACTH occurs well after the newborn period and thus is not helpful in making an early diagnosis.

**Figure 243-2** Diagnostic algorithm for a child with ambiguous genitalia with palpable gonads is presented for information only. This complex clinical situation requires the assistance of a pediatric endocrinologist for ultimate diagnosis. DSD, disorders of sex development; T/DHT, testosterone/dihydrotestosterone. (From Styne D. Pediatric Endocrinology. Philadelphia, PA: Lippincott Williams & Wilkins; 2004. Reprinted by permission.)

Stretched penile length in a term male infant should measure more than 2 cm; average length is approximately 3.5 cm. A normally formed phallus and scrotum indicates that testosterone production in the critical window of male differentiation was appropriate (around weeks 8 to 12 of gestation). Because further growth of the normally formed phallus is under the control of testosterone stimulated by fetal LH after midgestation (rather than hCG, which falls during this time), micropenis (penile length <2 cm) often indicates gonadotropin deficiency and may be a sign of hypopituitarism. Proper examination technique is critical because an infant with chordee or a generous suprapubic fat pad may be thought mistakenly to have micropenis. The position of the urethral meatus should additionally be noted, which sometimes requires observation of urination, because a urogenital sinus can sometimes be mistaken for the urethra and the indentation at the end of the glans penis can be mistaken for the opening of the penile urethra. The labioscrotal

folds should be examined for degree of fusion, as well as for symmetry, rugosity, and color. The presence or absence of a vaginal opening should of course be established. Gonads, when palpable bilaterally, are most often testes. A unilaterally palpable gonad may be a testis, an ovotestis, or an ovary. Sweeping the fingers down the path of the inguinal canal may allow palpation of gonads that could not otherwise be located. Physical examination may rule out certain diagnoses; for example, if gonads are palpable, the infant is not a virilized female with CAH because these children have gonads (ovaries) that are situated in the pelvis and are not palpable.

Nongenital anomalies on physical examination should also be noted and documented. Genital anomalies may occur in conjunction with an overall pattern of malformation or may be seen in certain syndromic diagnoses; dysmorphic features or specific nongenital anomalies may raise suspicion for one of these conditions. Again, discordance between the phenotypic sex

and genetic sex (known ahead of time as a result of prenatal testing) should raise suspicion for the possibility of DSD.

### Laboratory Evaluation

Basic serum chemistries should be obtained immediately to evaluate for salt wasting or hyperkalemia associated with CAH, but abnormalities may take days to become apparent. A karyotype will establish whether the child is genotypically XX or XY (or other) and should always be performed; although, it alone will not establish a diagnosis. Results from an urgently ordered karyotype can be available within approximately 3 days in some cytogenetics laboratories. Endocrine testing generally consists of measuring 17-OHP, testosterone, DHT, androstenedione, follicle-stimulating hormone, LH, and AMH performed in a national specialty laboratory with pediatric standards and sample sizes, rather than a local laboratory, which is most unlikely to have pediatric standards or appropriately sensitive techniques. Based on these results, additional tests may be performed. In the first weeks after birth, testosterone measurement may reveal the amplitude of the episodic spike of testosterone. After this period, hCG administration will help determine whether functional Leydig cells are present (given that functional cells will secrete testosterone in response to the hCG). Of course, serum testing of the steroid hormones involved in the pathways for cortisol and testosterone is indicated in many cases because rare forms of CAH will not uniformly cause elevations in 17-OHP levels. In some cases, stimulatory testing with ACTH is necessary to identify the defect.

Newborn screening for 21-hydroxylase deficiency (but not other forms of CAH) now occurs in all 50 states within the United States, as well as Washington, DC and Guam. Results can be returned several days after the specimens are drawn and are thus available within the first week of life, but not always before clinical symptoms develop. This screening test is most helpful in diagnosing the normal-seeming, but affected, male.

A trial of testosterone injections (eg, 25 mg of testosterone enanthate intramuscularly every month for 3 months) is given in some equivocal cases to assess whether phallus size responds to androgen, which may eliminate androgen resistance as a diagnostic possibility. However, the effect of this cannot be assessed for several months.

### Imaging

Imaging is useful to determine internal anatomy. Ultrasound examination, if performed by an experienced technician, determines the presence and appearance of Müllerian structures. Absent Müllerian structures imply that AMH was produced from testicular tissue and that the underlying problem is an abnormality of testosterone or DHT synthesis or action. Additionally, ultrasound is valuable in evaluating associated renal problems (seen in some syndromes such as Frasier syndrome) and for visualization of the adrenal glands. The gonads may be identifiable by ultrasound examination, although magnetic resonance imaging may be required, particularly if the gonads are intraabdominal.

## MANAGEMENT

A team approach is necessary to address the multiple issues surrounding management of patients with DSD. The team may consist of an endocrinologist, pediatric surgeon, pediatric urologist, neonatologist, and geneticist, as well as specialists in ethics, psychology, and social work. Gender assignment should be avoided while the evaluation is occurring, which may take days to weeks. Because CAH is the most common condition leading to ambiguous genitalia, a tendency may exist to tell parents that their child most likely has CAH. Guessing should be avoided because it potentially introduces confusion and may increase distress. The infant should be referred to using gender-neutral terms such as *your baby* or *the baby* rather than *he* or *she*. Completion of the birth certificate should be delayed, and the family should be supported by an experienced and well-trained social worker or psychologist. The ultimate gender assignment is based on many factors, including the underlying diagnosis, the genital appearance, surgical options, potential for fertility and sexual function, and the personal and cultural beliefs of the family.

When a gender assignment is reached, the gender role should be supported, although parents should understand that not all children with a given diagnosis will identify themselves in the same way over time. Because of this potential for discordance between assigned gender and later gender identity, surgical reconstruction of the genitalia is increasingly deferred until the child is able to participate in the decision-making process. Gender identity, the personal conception of oneself as male or female, is the result of a complex interplay between both biologic and environmental factors. It is distinct from sexual orientation and gender role. Hormonal effects (specifically androgen effect on the prenatal brain), brain structural differences, assigned sex of rearing, and sex-steroid effects at the time of puberty have all been shown to influence gender identity. Given this complexity, definitive predeterminations of gender identity are unlikely to ever be fully accurate, and a significant number of children who are assigned a particular gender are later dissatisfied. Unfortunately, outcome data for gender identity in DSD are relatively sparse. The largest study to date showed that genetic males with active prenatal androgen effects should be raised as males, given their high rates of male gender identity. Additionally, female infants virilized as a result of CAH should be raised female because more than 90% of these patients report satisfaction with an assigned female gender. However, gender identity outcomes are much more difficult to predict in other disorders, with high rates of gender change and gender dysphoria occurring with some diagnoses. This variability in gender identity again speaks to the reasoning behind deferring genital surgery in infancy.

In some instances, early surgery is indicated for medical reasons (as in the case of the long, common urogenital channel). The potential for malignant degeneration of a gonad (particularly in cases of 46,XY gonadal dysgenesis) must also be considered. Prophylactic gonadectomy was previously performed early in all cases of 46,XYDSD; now, tumor risk is predicted

based on molecular diagnosis. Guidelines for timing a gonadectomy have been proposed, but consensus is needed.

Long-term psychological support is required for most children with DSD. Help should be provided to the child by a mental health professional, preferably someone with experience in dealing with DSD. National and local support groups may provide information and support and may further assist with issues of gender identity and sexuality. Historically, there has been stigma associated with DSD, and care should be taken by the physician to reassure the family that there should be nothing stigmatizing or shameful about the DSD diagnosis. The genitalia may seem atypical but are the normal consequence of the underlying biologic pathways. The underlying condition and management (including surgical decisions) should be discussed with the child over time in an age-appropriate manner, just as one would when treating other chronic medical conditions.

## CONCLUSION

The differential diagnosis of the baby born with developmental anomalies of the external genitalia is extensive, given the complicated process of human sexual differentiation. The birth of such children naturally creates a stressful situation for the family which can be attenuated by the appropriate evaluation and management by an experienced multidisciplinary team. Because fatal results may occur with improper vigilance, hospitalization and close monitoring of the baby are indicated in all cases. Given that a child's gender identity cannot be predicted based solely on the underlying disorder or genital appearance, gender assignment requires careful consideration. In some cases, the assigned gender may not be concordant with the child's gender identity as the child ages. Throughout this process, the general pediatrician plays an important role in helping coordinate the care of these children.

## WHEN TO REFER

Given the possibility of significant electrolyte disturbances, cortisol insufficiency, and possible shock and death, all children with ambiguity of the external genitalia should be evaluated immediately by an experienced multidisciplinary team that includes a pediatric endocrinologist. In many cases, this process necessitates transferring the child to a medical center with a neonatal intensive care unit and the appropriate pediatric subspecialists. The child should never be sent home and referred to subspecialty care as an outpatient.

Indications for referral include the following:

All patients with genital ambiguity

Male-seeming infant with

- Bilateral nonpalpable testes
- Micropenis
- Perineal hypospadias
- Single undescended testis with hypospadias of any degree

Female-seeming infant with

- Clitoral hypertrophy of any degree
- Posterior labial fusion (not adhesion)
- Inguinal or labial mass

Patient with family history of DSD

Patient with discordance between genital appearance and prenatal karyotype

## Chapter 244

# DOWN SYNDROME: MANAGING THE CHILD AND FAMILY

Marilyn J. Bull, MD

## INTRODUCTION

Primary care physicians (PCPs) are key professionals in the medical care of children with Down syndrome (DS), because they are best able to provide a medical home for the child and family. Caring for children with DS and their families requires long-term commitment and interest on the part of the PCP to ensure that such children realize their full potential and that families receive the support and education they need. This chapter provides current information about the special health care needs of children with DS and guidelines for meeting these needs. The guidelines also include coordination of care with medical subspecialists and early childhood educators.

## ETIOLOGY

DS is caused by a chromosomal abnormality called *trisomy 21*. Most individuals (95%) with trisomy 21 have 3 copies of chromosome 21; in approximately 5% of patients, 1 copy of chromosome 21 is translocated to another chromosome, most often chromosome 14 or 21. In 2% to 4% of cases with trisomy 21, mosaicism is recognizable with both a trisomic and a normal cell line present. Determining the genotype of a child with DS is important, because the recurrence risk for a subsequent pregnancy varies depending on the type of chromosome abnormality present.

### Origin of Trisomy 21

Trisomy 21 most commonly occurs because of an abnormality in chromosome replication. The abnormality, known as *nondisjunction*, occurs during meiosis. Normally during meiosis the process of disjunction reduces the number of chromosomes in the germ cell (sperm and ovum) from 46 to 23. At fertilization, the egg and sperm unite, giving the developing fetus the full complement of 46 chromosomes in 23 pairs. Nondisjunction is the abnormal division of the 46 chromosomes in the egg or the sperm, resulting in 1 carrying 24 chromosomes. At fertilization, the germ cell with 24 chromosomes unites with the germ cell with 23 chromosomes, resulting in a total of 47 chromosomes. DNA testing has shown that nondisjunction of chromosomes in the 21 group, responsible for 95% of cases of DS, occurs in the egg 95% of the time. The recurrence of DS in subsequent pregnancies for nondisjunction trisomy 21 is approximately 1 in 100 for women younger than 35 years, and is age related for older women.

A small group of patients with DS with trisomy 21 (2%–3%) have a mixture of cell types (mosaicism), some cells with 46 chromosomes and some with 47. The proportion of trisomic cells to cells with normal chromosomes can vary greatly from person to person and from tissue to tissue in the same person. The mosaicism is usually detected in the lymphocytes from a peripheral blood sample; thus, tests on other tissues are unnecessary. In some instances, cultures of fibroblasts found on skin biopsy are analyzed when low-level mosaicism is suspected. Experts do not know if any tissues are spared of trisomy cells. This mosaicism often results from an error in maternal meiosis and only in a few cases occurs after fertilization because of an error in mitosis. The mosaic type of DS may have less distinct physical features and, in most cases, show higher intellectual function, depending on the percentage of cells with trisomy 21. Very low levels of trisomy 21 cells are reported in patients with DS with higher intellectual function.

### Origin of Translocation Trisomy 21

*Translocation* refers to a chromosome rearrangement in which part of the extra chromosome attaches to another chromosome. In the case of DS, the long arm of one chromosome 21 attaches to another chromosome 21, 22, or 14. The karyotype shows the number of chromosomes as 46 and shows the abnormally attached additional chromosomal material. In one-third of cases of 14:21 translocation-type DS, one of

the parents is a carrier of a balanced translocation. The mother is the carrier in 90% of these cases. The remaining two-thirds of cases of 14:21 translocation type DS are *de novo*, with the translocation occurring in the noncarrier mother's egg cell during meiosis. In children with a 21:21 translocation, 93% of cases are *de novo* translocations. In *de novo* cases, the 21:21 translocation occurs because of a meiotic error in the egg cell. In about 7% of cases, the 21:21 translocation is the result of a balanced translocation in a carrier parent. In cases in which the 21:21 translocation is passed from carrier parent to child, the carrier is equally likely to be the mother as the father. All of these types of DS produce a similar range of clinical features, but the recurrence risk is higher for the translocation types of DS. Genetic counseling is therefore extremely important.

### Molecular Pathologic Features of Trisomy 21

The DNA sequence of chromosome 21 is now known, and between 200 and 300 genes have been identified. A DS-critical region on the long arm (q arm) has been identified; however, other genes outside this region of chromosome 21 also contribute to the clinical features of DS. This finding strongly suggests that DS is a contiguous gene syndrome with triplicate gene dose effects. This makes it unlikely that a single DS chromosomal region is responsible for most of the DS phenotypic features.

In fact, the variability in clinical features of DS among affected individuals is likely related to polymorphisms in nonchromosome 21 genes as well as to epigenetic factors. A few genes associated with particular characteristics of DS have been identified. For example, polymorphisms in the *DSCAM* gene on chromosome 21, which encodes a neural cell adhesion molecule, have been implicated as conferring an increased risk of Hirschsprung disease in individuals with DS and those without DS. The  $\beta$ -amyloid precursor protein (APP) has been implicated in the increased risk of early-onset Alzheimer disease in the DS population. Genome-wide association studies have revealed genetic loci on chromosome 21 and other chromosomes associated with an increased risk of atrioventricular cardiac septal defects. Moreover, there is emerging evidence of the role of epigenetic factors in the etiology of DS, as meta-analyses suggest that a lack of folic acid supplementation during the periconception period may result in aberrant methylation and increase the risk of meiosis II errors causing DS. Furthermore, methylation patterns in blood samples from individuals with DS demonstrate several regions of differential methylation across the genome, including chromosome 21, and involving genes important in the development and regulation of chromatin structure in particular. These are all areas of active research.

## INCIDENCE AND PRENATAL DIAGNOSIS

By current national prevalence estimates, DS occurs in approximately 1 in every 700 to 800 births. The incidence of DS is closely related to the age of the mother, and the likelihood of bearing a fetus with DS increases when the mother is older than 35 years. Recent advances in technology have improved screening and

diagnostic testing for identifying fetuses with DS. Recently, diagnostic prenatal testing of cell-free DNA from the plasma of the pregnant mother has become available as an option for screening for aneuploidy in women at increased risk. Regardless of maternal age, the American College of Obstetrics and Gynecology recommends a discussion of the risks, benefits, and alternatives of various methods of prenatal screening and diagnostic testing, including the option of no testing, with all patients. Additional prenatal diagnostic testing for the fetus diagnosed with DS, including fetal echocardiogram, can greatly improve the outcome for the mother and the infant.

## DIAGNOSIS

The birth of a child who has DS presents many issues of importance in the clinical care of the infant and for the family. The first critical task is making an accurate and prompt diagnosis, and the most sensitive test in the first 24 hours of life is the physical examination. Multiple features enable the experienced physician to suspect the diagnosis of DS. Some of the most common physical features include hypotonia, a relatively small brachycephalic head, epicanthal folds, flat nasal bridge, upward-slanting palpebral fissures, Brushfield spots, small mouth, small and often square shaped ears, increased skin at the nape of the neck, a single transverse palmar crease, and short fifth finger with clinodactyly. The degree of intellectual disability can only be determined with time, and although most individuals with DS have milder forms of intellectual disability, some may be more significantly affected. According to the *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition*, health professionals must consider the person's ability or impairment across 3 skill areas: conceptual, social, and practical life skills. Most individuals with DS have mild forms of intellectual disability, although the degree of disability varies greatly among individuals with the condition.

The prenatal diagnosis of DS is increasingly common. If chromosome analysis was performed, the results should be reviewed with the family and the report added to the infant's medical record. If the results of prenatal chromosome testing are not available, a blood sample should be obtained for postnatal cytogenetic analysis to confirm the diagnosis and rule out a chromosome translocation. If there was no prenatal diagnosis and the infant is clinically suspected of having DS, a blood specimen should be obtained for a chromosome analysis and rapid results requested. Results of fluorescence in situ hybridization (FISH) analysis should be available within 24 to 48 hours; if analysis confirms that an extra chromosome 21 is present, a complete chromosome analysis must be obtained to determine if a translocation is present. A detailed family history should also be obtained. The confirmation of DS diagnosis by chromosome analysis helps the parents accept the clinical diagnosis and forms the basis of genetic counseling for the parents regarding the risk of recurrence.

The first important aspect of helping families with an infant with suspected DS is to congratulate them on the birth of their infant. Ideally both parents, or the mother and a significant other, are present and the

delivery of the news for the child with the suspected diagnosis is coordinated by the obstetrician and pediatrician. The diagnosis should be given as soon as possible after the mother has recovered from the immediate delivery, in a private setting by the physicians familiar with the patient.

As soon as the diagnostic FISH and karyotype results are available, the results should be shared with the parents and the clinical manifestations of DS should be reviewed. The parents should be referred for genetic counseling if they were not seen by a genetic counselor prenatally.

A referral for parent-to-parent contact and local and national parent support organizations is helpful for prospective and new parents of a child with DS. It is also important for physicians to know that in several states they are legally mandated to connect parents to official information sources about DS. (See Tools for Practice: Engaging Patient and Family.)

Present the expectations for a child with DS to the family and enable them to learn the realities and possibilities for a healthy and productive life for the child. Share with families how, when, and what to tell siblings, family, and friends about the diagnosis. Assure them that resources and guidance to assist in the care of a child with long-term disabilities are available. Encourage them to enjoy their newborn. Discuss the efficacy and availability of early intervention resources in the community, and facilitate referrals as appropriate.

Arrange for a follow-up meeting with the family to give them time to begin adjusting to the new information and to formulate questions. Offer to meet extended family members to answer questions. Because newborn hospital care is often provided by a physician who is not part of the infant's medical home, it is important to ensure appropriate communication to provide a smooth transition for the family.

## Adoption

Most families are able to meet the needs of their child born with DS. Some families have greater initial difficulty and require more extended counseling. In rare cases, a family will not be able to accept a child who has DS. In this event, adoption should be discussed. In many instances, families are waiting to adopt children who have DS, and families with one child with DS may wish to adopt another. The National Down Syndrome Adoption Network can be contacted for information ([www.ndsan.org](http://www.ndsan.org)).

## HEALTH SUPERVISION

Early detection and correction of medical problems seen in children who have DS is important to minimize complications and optimize the child's potential growth and development. Children with DS require the usual preventive interventions and anticipatory guidance given to other children and families, but the special problems of children who have DS require additional evaluation and close monitoring.

## Birth to 1 Month of Age

When the clinical diagnosis of DS is considered, rapid chromosome testing is ordered, and the family is

counseled regarding the suspected diagnosis. Careful assessment of the infant is indicated.

### **Congenital Heart Defects**

Approximately 50% of infants with DS have congenital heart defects. An echocardiogram should be obtained for all infants and interpreted by a pediatric cardiologist. This is important even if a fetal echocardiogram had been done. All infants with an abnormal postnatal echocardiogram should be referred to pediatric cardiologist.

### **Gastrointestinal Problems**

Gastrointestinal problems, present in 15% of children with DS, may be evident very early in the newborn period or manifest later in infancy. Duodenal atresia, tracheoesophageal fistula, anorectal stenosis or atresia or Hirschsprung disease, and malrotation occur with increased frequency in children with DS. Appropriate evaluation and treatment should be instituted promptly if symptoms are present.

Constipation is common and often associated with a limited fluid intake, restricted diet, and hypotonia. Many infants require treatment with a stool softener. Hypothyroidism, gastroesophageal malformations including stenosis, and Hirschsprung disease (2%) should be considered if constipation is refractory to usual treatment.

### **Feeding Problems**

Most infants with DS can breastfeed successfully. Some will need supplementation with a bottle or tube until a successful nursing pattern is established. Infants who sleep for prolonged periods need to be awakened for feeds to ensure adequate caloric intake. Feeding may be facilitated by ensuring that nasal passages are clear and providing chin support for infants with low tone. Infants with feeding problems need to have weight gain monitored closely; if difficulty with nursing occurs, referral to a lactation consultant may be helpful.

Infants with hypotonia and slow feeding, choking with feeds, recurrent pneumonitis or other recurrent or persistent respiratory problems, or unexplained failure to thrive should be referred for a radiographic swallowing assessment. Alternative feeding methods should be used for infants at risk for aspiration until they mature and the difficulty has resolved.

### **Ophthalmologic Problems**

Assess infants with DS for the presence of a red reflex. Cataracts and congenital glaucoma occur with increased frequency and require treatment by an ophthalmologist with experience in managing children with DS.

### **Hematologic Abnormalities**

Leukemoid reactions and transient myeloproliferative disorder (TMD) are relatively common, occurring in about 10% and seen almost exclusively in newborns with DS. Polycythemia is also relatively common. Obtain a complete blood count and follow subspecialty recommendations for management. TMD usually resolves spontaneously but carries a 10% to 30% risk of later onset of leukemia.

Parents are often concerned about the increased risk of leukemia in children with DS, which occurs in only about 1% of these children. Parents should be counseled regarding the signs of easy bruising, petechiae, lethargy, or changes in feeding patterns, which could be early signs of leukemia.

### **Respiratory Complications**

Problems with breathing, including stridor, noisy breathing, upper airway obstruction with retractions, or wheezing, should be referred to a pediatric pulmonary specialist. Intubation may also be more difficult, because tracheal anomalies including tracheal rings and small tracheal size occur at an increased frequency.

Hearing should be evaluated at birth following universal newborn hearing screening guidelines, and any needed follow-up assessment should be completed by 3 months.

### **Congenital Hypothyroidism**

Obtain thyroid stimulating hormone (TSH) concentration if state newborn screening only measures free thyroxine (T4) to avoid missing congenital hypothyroidism, which occurs in approximately 1% of infants with DS. The management of children with abnormal thyrotropin or T4 levels should be discussed with a pediatric endocrinologist.

### **Atlantoaxial Instability**

Explain to parents the importance of cervical spine positioning precautions to avoid excessive extension or flexion. Atlantoaxial instability refers to backward movement of the odontoid process of the axis, which may compress the spinal cord and result in the signs and symptoms of cord compression including neck pain, head tilt, progressive weakness, and loss of bladder or bowel control. Neurologic examination reveals long-tract signs such as increased deep-tendon reflexes in the lower extremities, a positive Babinski sign, and ankle clonus.

Atlantoaxial subluxation is a neurosurgical emergency requiring immediate referral and treatment. Although atlantoaxial subluxation occurs in only 1.5% of children who have DS, it can be life threatening and may cause irreversible disability if not treated promptly. Any child with complaints of neck or radicular pain, weakness, spasticity or change in tone, gait difficulties, hyperreflexia, or change in bowel or bladder function must undergo plain cervical spine radiography in the neutral position. Refer caregivers to a pediatric neurosurgeon or pediatric orthopedic surgeon experienced in managing DS in children if plain cervical spine radiography in the neutral position is abnormal.

Routine radiographs of the cervical spine are no longer recommended as they do not predict well which children are at an increased risk of developing spine problems.

Furthermore, adequate vertebral mineralization and epiphyseal development for accurate radiographic evaluation of the cervical spine does not occur until 3 years of age.

The protection of the cervical spine during any anesthetic, surgical, or radiographic procedure is

important, but parents also need to be reassured that normal care, including therapy to develop head control, is not dangerous and is important for normal development.

### **Complementary and Alternative or Integrative Therapies**

Discuss with parents treatments that are considered integrative, and facilitate their understanding of which therapies are recognized to be safe and which are potentially dangerous.

Many families have questions about cognitive and developmental improvement with supplemental vitamins or with vitamins and minerals in high dosages. However, no studies have validated that improvement occurs, and there are known side effects of high doses of some vitamins. Care should be taken to ensure that parents understand the risks and that excessive doses are avoided.

### **1 Month to 1 Year of Age**

In many cases, families who have a child with DS need to see the PCP frequently for medical care and education. The parents' anxiety and questions decrease with time, but for the initial few months they need to be able to depend on the availability of their medical home for their needs. Ensuring that there are adequate time and resources in a busy office can be challenging, and using a system of care for the child with special health care needs (CSHCN) is important. Consultation with a dietician, nurse practitioner, or social worker can supplement the specialized care helpful to a family with an infant with DS. It is important to schedule a follow-up visit soon after hospital discharge for an assessment of the infant's progress and to provide the family an opportunity to discuss questions and concerns. Follow-up visits should include an assessment of the emotional status of the parents, adjustment of the siblings, and the effect of the baby on interfamilial relationships. Connection to early intervention services and their relationship to the needs of the infant and family should be reviewed.

During the first year, the family's understanding of the risk of recurrence of DS and the availability of prenatal diagnosis should be reviewed and a referral made for genetic counseling if not already provided.

Families should be encouraged to discuss questions they may have regarding therapies that are considered integrative at each well-child visit.

### **Growth and Nutrition**

Discuss feeding and nutritional intake carefully in the first visits, and routinely in each health care visit. Monitor weight and weight-for-height trends closely. Plot growth parameters using the standard growth charts of the National Center for Health Statistics or the World Health Organization. Previously used DS growth charts no longer reflect the current population of children. New DS growth charts have been developed, and patterns of growth can also be followed on the DS-specific growth charts.

### **Hearing**

Serous otitis media and associated fluctuating hearing loss are extremely common in young children with DS

(50%–70%). Infants who passed the newborn hearing screen should be reevaluated at age 6 months and every 6 months subsequently until they are able to participate reliably in ear-specific testing with headphones, usually after age 4 years. Any child who fails a hearing screen should be evaluated by an otolaryngologist comfortable with examining infants with stenotic ear canals to determine if middle ear problems are present.

### **Vision**

Within the first 6 months of life, infants with DS should be examined by a pediatric ophthalmologist or an ophthalmologist with expertise in caring for infants with disabilities to assess for cataracts, nystagmus, and strabismus. Lacrimal duct obstruction is also common because of the craniofacial configuration in DS; infants should be referred for surgical repair if any obstruction is not resolved by 9 to 12 months of age.

### **Thyroid Disease**

Repeat TSH testing at age 6 months, age 12 months, and annually thereafter because symptoms of hypothyroidism may be confused with unrelated findings seen commonly in children with DS.

### **Obstructive Sleep Apnea**

Children with DS are at an increased risk of obstructive sleep apnea, so the symptoms should be discussed. Any child with heavy breathing, snoring, restless sleep, uncommon sleep positions, frequent night awakening, daytime sleepiness, apneic pauses, and behavior problems that could be associated with poor sleep should be referred to a pediatric sleep laboratory for a sleep study or polysomnogram. Because the correlation between parent report of sleep obstruction symptoms and polysomnogram results is poor, it has been recommended that every child with DS be referred if possible for a sleep study by age 4 years. In addition, families should be counseled on obesity as a risk factor for obstructive sleep apnea.

### **Mortality**

Medical care for infants in this age group who have DS involves particular diagnostic and consultative procedures, given that more than 50% have serious medical disorders as a component of their condition. The first year of life holds the highest probability of death for children with DS who have an additional anomaly. Approximately 78% of infants with an additional anomaly survive, and 96% without an additional anomaly survive. Survival of children with cardiac malformations has improved, with only 8% to 9% mortality now being reported in children with DS and heart defects. Leukemia is a cause of death in less than 10% of cases.

### **Questions**

During office visits for periodic health assessments, the PCP should ask about the infant's feeding and discuss enrollment in an early education program. Extra time should be arranged at office visits to allow families to talk about how they are adjusting. The physician should review with them information about DS

provided earlier. The family should also be informed about Supplemental Security Income (SSI) and other programs that offer financial aid to help families with the extra costs of raising a child who has special needs. Parents of infants who have DS often ask questions about tongue protrusion. Contributing factors include hypotonia, a relatively small oral cavity, and upper airway obstruction with mouth breathing. Behavior-management techniques can be used to help manage tongue protrusion; for some children, oromotor exercises may be helpful.

Many families seek hope for an improvement of appearance and function for their child with DS through surgical and medical interventions. Tongue resection to improve speech, silicone implants to correct micrognathia, and surgical interventions for eye appearance have been implemented. The PCP should discuss these interventions when they are considered by the family and be prepared to communicate the risks and benefits of any surgical procedure. For example, no improvement in speech after tongue resection has been observed.

### 1 to 5 Years of Age

Children with DS need annual health assessments. At these office visits, the PCP should inquire about the caregiver's concerns and review the health supervision issues specific to children with DS.

### History and Anticipatory Guidance

A full history and physical examination should include attention to nutrition and growth. Height, weight, and weight for height or BMI should be plotted on the World Health Organization or US Centers for Disease Control and Prevention (CDC) growth charts. The new DS-specific charts can also be used to follow patterns of growth. Changes in diet may be recommended to ensure that the child receives adequate calcium, vitamin D, and iron, and that the fat content of the milk is appropriate for the child's weight for height or BMI. For children who are picky eaters, are unable to chew meat, or do not have an adequate intake of iron-containing foods, a complete chewable multivitamin that contains iron may be crushed and added to food.

Children with cardiac lesions should maintain follow-up with a pediatric cardiologist even after cardiac repair to monitor for residual lesions or the development of pulmonary hypertension.

Monitoring for strabismus and ensuring every child is seen at least annually until age 5 years for ophthalmologic assessment is important. The development of refractive errors and strabismus during preschool years is common, and children with these issues benefit from early detection and treatment.

Fluctuating hearing loss associated with serous otitis media is common in DS. Tympanometry and a behavioral audiogram should be arranged every 6 months until the child is capable of ear-specific audiologic testing, which is usually around age 6 years.

Continue to ask about heavy breathing, snoring, restless sleep, daytime sleepiness, apneic pauses, uncommon sleeping positions, and behavior problems that could be associated with poor sleep, and refer as

appropriate. The strong correlation between obstructive sleep apnea, cognition, and behavioral problems makes detection important. A sleep study is recommended for all children with DS by age 4 years.

A dental examination is recommended twice a year beginning at the first birthday. It is helpful to remind parents that delayed and irregular dental eruption and hypodontia are common in children with DS.

Discuss with caregivers and model the use of accurate terms for genitalia and private body parts. Teach the child and family that the only reason for viewing or touching private body parts is for doctor visits or bathing and showering.

It is also important to discuss with caregivers the increased risk of sexual exploitation and educate them that most commonly the perpetrators are people the child knows and trusts.

As discussed in previous visits, future pregnancy planning, recurrence risk, and resources for prenatal diagnosis should be provided during at least one visit when the child is between 1 and 5 years.

It is important to review the signs and symptoms of spinal cord compression associated with atlantoaxial instability and remind caregivers to contact a physician experienced with the condition immediately if they have concerns about possible symptoms.

Other topics to review include questions regarding integrative (complementary and alternative) therapies and eligibility for SSI, Medicaid, and any other needed social service benefits.

### Laboratory Tests and Vaccines

TSH screening should be performed annually, or sooner if symptoms of thyroid dysfunction occur.

A hemoglobin screening should be performed annually for all children, as well as ferritin and C-reactive protein screening for any child at risk of iron deficiency on the basis of decreased iron intake.

All routine immunizations should be provided and an influenza vaccine should be given annually to the child and encouraged for all household contacts. Ensure that children with respiratory and cardiac problems receive all recommended vaccines.

Children with symptoms potentially related to celiac disease and who are on a gluten-containing diet should have screening with a tissue transglutaminase immunoglobulin A (IgA) level and simultaneous serum IgA. Symptoms are varied and include diarrhea, protracted constipation, slow growth, unexplained failure to thrive, anemia, abdominal pain or bloating, and refractory developmental or behavioral problems. Patients with abnormal values should be referred for specialty assessment. There are no data and no consensus that patients with normal data on an initial evaluation warrant further laboratory tests.

### Early Intervention and Education

Review involvement in early intervention programs and therapy as indicated. Assess the involvement of caregivers in the child's developmental program and also the needs of the child and family related to the child's strengths and weaknesses. For children younger than age 3 years, review early intervention including physical, occupational, and speech therapy. It is helpful

to review the importance of caregiver involvement in the process. Discuss the transition from early intervention to preschool at the 30-month visit, because the family needs to understand the change from the Individualized Family Service Plan (IFSP) to the Individualized Education Plan (IEP) in public education.

The PCP needs to review the current IEP for children older than 3 years to ensure that the developmental program is appropriate and that the parents have had an opportunity to provide input in the IEP process. School problems may come to the physician's attention more often when children who have DS are placed in mainstreamed or regular classes. Typically developing children are excellent role models for children with DS, but additional supports in the school environment are often required. School learning problems require further evaluation. The history should be reviewed thoroughly to ensure that the parents' and teachers' expectations are appropriate for the child's developmental age and that appropriate educational interventions are selected for the child's specific learning style. Resources for teachers and caregivers that are specific to children with DS are available and referenced in the Tools for Practice section. Medical problems that can affect learning and behavior should be identified. For example, hearing and vision need regular evaluation as outlined previously, and methods of communication that are developmentally appropriate for the child should be integrated into the program.

### **Autism in Down Syndrome**

Children with DS are recognized with increasing frequency to have symptoms attributable to autism and may be diagnosed with autism spectrum disorder. This diagnosis can be challenging, because the findings are often attributed to DS alone and the assessment is most effective when done by a physician experienced in both DS and autism. The diagnosis should be considered whenever social and communication skills lag significantly behind those expected for the child's general developmental level.

### **Behavior Problems**

The PCP also should ask about behavior problems. The personalities of many children who have DS may not fit the stereotype of being placid or compliant, and parents may not volunteer information about obstinacy or noncompliance. When parents express concerns about behavior, a thorough history should be obtained, and the parents should be asked about changes in the environment or their expectations. A complete physical examination should be performed and laboratory tests performed, if warranted, to identify medical problems that may lead to behavior disorders. A trial of behavior management should be initiated for mild problems, and the diagnoses of autism or physical abuse should be considered. For severe behavior problems or persistent mild to moderate problems that have no apparent medical cause, the child should be referred to a behavior specialist familiar with behaviors seen in children with DS. In addition, an assessment for celiac disease should be considered for children with difficult-to-manage behavior problems.

## **5 to 13 Years of Age**

The child with DS should be seen for an annual health care visit that incorporates all aspects of well-child health supervision. The PCP may also receive many questions regarding behavior, nutrition, activity, and educational interventions for the child with DS. Social opportunities for children with DS often become more challenging as they grow older, and the family will benefit greatly from the advice of the trusted physician.

### **History and Anticipatory Guidance**

The comprehensive well-child visit for a child with DS should include a complete history, review of systems, and physical examination. Nutritional assessment should include plotting weight, height, and BMI on the CDC National Center for Health Statistics growth charts. New DS-specific charts have been developed that can also be used to follow patterns of growth. Monitoring weight and activity is extremely important at these ages because lifetime eating patterns are best established in childhood.

Hearing assessments should be made every 6 months until the child is able to accomplish ear-specific testing (usually around age 6 years). Hearing testing annually thereafter is important for development of optimal speech and communication.

An ophthalmologist experienced in caring for children with disabilities should perform a visual assessment every 2 years or more often, if problems are identified.

Evaluate the child for dermatologic problems, and remind the family that both cardiology follow-up as indicated and an annual dental evaluation are important.

The physical examination should be performed with particular attention to myelopathic signs. Review with parents the universal precautions for the protection of the cervical spine during anesthetic, surgical, or radiographic procedures. The PCP should be contacted immediately in the case of new onset of symptoms of myelopathy.

As children become involved with organized sports, parents should be advised that some contact sports may place children at increased risk of spinal cord injury. Football, soccer, and gymnastics for older children should be considered with caution; trampolines should be avoided unless under direct professional supervision. The Special Olympics has specific screening requirements for participation by all athletes. Review with caregivers any concerns about sleep including snoring, restless sleep, unusual sleep positions, and other concerns about sleep apnea. Discuss obesity as a risk factor for obstructive sleep apnea.

## **13 to 21 Years of Age**

Adolescence is a special challenge for any family. The physical, emotional, and educational needs in adolescents who have DS, however, require a special approach. During the annual health assessment visit, the PCP should discuss with the family their child's health, educational program, behavior challenges, and long-term plans for guardianship and care.

### **History and Anticipatory Guidance**

The comprehensive assessment needs to include an evaluation of nutritional status. Height, weight, and

BMI plotted on a standard CDC growth chart are an essential component of this evaluation, and the new DS-specific charts can also be used to follow patterns of growth. Nutritional counseling and evaluation of activity are extremely important, and it is helpful to include signs and symptoms of sleep disorder and the added risk of obesity for sleep apnea in the discussion.

The pediatrician should annually review with the patient and family the potential symptoms related to atlantoaxial instability and perform a careful examination for myelopathic signs. Prompt referral for assessment by a physician experienced in the disorder can minimize long-term disability. Continued emphasis on healthy lifestyle is important, and the Special Olympics can provide excellent opportunities for activity. The Special Olympics has special health screening requirements for all athletes.

At this age, it is critical to discuss current educational planning and its appropriateness for the individual. A discussion of training for adult life and planning for transition to adulthood is an essential component of the planning process. Explain the process of arranging for guardianship by age 18 years as appropriate, and discuss financial planning including enrollment in Medicaid and SSI. Families also benefit from recommended continuing speech and communication therapy for optimal functional skill development.

The PCP and family should also discuss a plan for the adolescent's living arrangements. Most communities have a spectrum of community living facilities that range from small, heavily supervised group homes to apartments that have minimal supervision. Families need to make living arrangements 3 to 6 years before they anticipate the need because there is often a waiting list for placement in a community facility.

A review of behavior and social development is important, and a child with any acute deterioration in function should be referred for assessment. Any history of possible seizures is an important consideration. Discuss normal and typical sexual development and behavior and provide understandable information on sexuality. It is essential for the family to receive information about contraception and prevention of sexually transmitted infections in both boys and girls at this age. The risk of having a child with DS should be discussed with girls. Although male patients with DS are usually infertile, instances of reproductive capability in men have been reported. Girls should receive routine gynecologic care, and any premenstrual behavioral concerns and menstrual hygiene issues should be reviewed.

Every young person and his or her family should be encouraged to continue to increase their development of independent hygiene and activities of daily living. Families appreciate counseling about teaching their child to avoid tobacco and drug abuse.

Additional medical considerations include a review of the cardiac history and an evaluation of older patients for acquired mitral valve and aortic valve disease, symptoms potentially related to celiac disease, and an annual TSH and hemoglobin screening. Ferritin and CRP screening should be performed for anyone at risk for iron deficiency. An annual review of immunization status and an influenza vaccine should continue.

A consultation for eye examination should occur every 3 years unless indicated sooner on the basis of ophthalmologist recommendations. Special attention should be given to ophthalmologic problems that typically occur after puberty, including cataracts, refractive errors, and keratoconus.

The family should be reminded to obtain an ear-specific audiogram and dental examination annually or sooner, if recommended by the specialist.

The transition to adult care is an important conversation to have with families. For many patients, identifying providers of adult subspecialty care can be challenging. Pediatric PCPs often continue to monitor adolescents into early adulthood to provide continuity of care. This can be helpful while the subspecialty care is established. Families are often attached to the pediatric PCP, and the discussion of adult care must center on aspects of preventive medical care for the young adult.

## ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Melissa Parisi, MD, FAAP, to this chapter's discussion of epigenetics.

## Chapter 245

# DRUG ERUPTIONS, ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME

Lauren Henderson, MD; Judith V. Williams, MD

Adverse drug reactions are seen in 1.5% of children in the outpatient setting and 11% of hospitalized children; they account for 2% of pediatric hospitalizations. The clinical expression of drug eruptions is extremely varied and includes rashes of varying morphology, symptoms, and associated conditions (Box 245-1).

This chapter discusses the types of drug eruptions seen most commonly in children: exanthematous, urticarial, serum sickness-like reactions, drug reaction with eosinophilia and systemic symptoms (DRESS; also known as drug-induced hypersensitivity syndrome [DIHS]), acute generalized exanthematous pustulosis (AGEP), erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN).

## EXANTHEMATOUS ERUPTIONS

### Etiology

Exanthematous eruptions represent the most common cutaneous expression of a drug reaction. Historically, these were known as morbilliform (measles-like), because they were clinically indistinguishable from viral causes. Although a variety of drugs can cause this reaction, the drugs that cause exanthematous or urticarial eruptions most often are listed in Box 245-2.

### History

A drug-induced exanthematous eruption often begins within 1 to 2 weeks after starting the drug, but delayed reactions can occur as late as 1 to 2 weeks after the drug is discontinued. Because no single laboratory test can identify the responsible drug, heavy reliance is placed on the history. Children simultaneously receiving more than 1 drug present a problem. In trying to select a single drug from a list, the 2 variables to consider are the temporal relationship between the administration of the drug and the onset of the rash, and the

NSAIDs, nonsteroidal anti-inflammatory drugs.

<sup>a</sup>Ranked from highest to lowest rate of reaction

Derived from Bigby M. Rates of cutaneous reactions to drugs. *Arch Dermatol*. 2001;137(6):765–770.

likelihood that a given medication can cause a drug eruption. For the latter variable, the specific drug incidence rates provide vital information regarding the most common causative drug. Aminopenicillins have the highest rate of reaction per recipients (4.4–8.0/100), followed by sulfonamides (2.5–3.7/100), while diazepam has the lowest rate (0.04/100). A concurrent viral infection can increase the chance of an exanthematous drug eruption, as in the commonly reported rash seen in children with Epstein-Barr virus following ingestion of amoxicillin. Most of these are morbilliform in nature. Their pathogenesis remains to be elucidated, but some studies suggest that an enhanced reaction to drug metabolites during an active viral infection results in cytotoxicity against infected cutaneous cells.

### Physical Findings

This type of eruption is generalized and consists of brightly erythematous macules and papules that tend to be confluent over large areas. It usually starts centrally on the trunk and spreads distally, with the legs being the last to become involved and also the last to clear. Palms and soles can be affected, but mucous membranes are usually spared. Pruritus is a common symptom, but not diagnostic. Drug fever has been well described, but most common exanthematous drug eruptions are not accompanied by an elevation in body temperature.

### Differential Diagnosis

For a generalized exanthematous eruption, the major differential diagnosis is a viral exanthem, drug reaction, or toxic erythema. A drug eruption may be more erythematous and confluent than a viral exanthem, but not always. Other clinical information can help establish the diagnosis, including a drug history and the presence or absence of other signs and symptoms of a viral infection. Acute and convalescent serologic tests can be obtained for some viral infections to provide a retrospective diagnosis.

In most cases, a presumptive diagnosis is made based on clinical data. Examples of toxic erythema are scarlet fever, staphylococcal-induced scarlatiniform eruptions, and possibly Kawasaki disease. Features that help distinguish these toxic erythemas from drug eruptions include a sandpaper-like roughened texture of the rash, mucous membrane involvement (scarlet fever and Kawasaki disease), fever, a focus of infection, and lymphadenopathy. Postinflammatory desquamation from the skin of the hands and feet often follows the rash of toxic erythema, but this sign is nonspecific. Drug eruptions as well as viral exanthems can involve the hands and feet, particularly the palms and soles. If the inflammation has been sufficiently intense, fine desquamation may follow.

### Laboratory Studies

Peripheral blood eosinophilia can occur during a drug eruption, but it is not diagnostic because eosinophilia can be seen in patients with allergic disease in general. The presence of eosinophils in a skin biopsy of the rash suggests a drug eruption. Unfortunately, no laboratory test at this time can incriminate a specific drug. In vitro tests to evaluate the cause of drug hypersensitivity reactions are an active area of

research; however, they are not developed sufficiently to be useful in clinical decision making.

For some drugs that can produce significant reactions in children with certain human leukocyte antigen (HLA) types, genetic pre-therapy testing can predict which children may be more susceptible to developing a drug reaction (clin pharmacol). The US Food and Drug Administration (FDA) recommends testing for HLA-B\*1502, particularly in individuals of Asian ethnicity, before starting carbamazepine to avoid developing SJS. Testing for HLA-B\*5701 can be done prior to starting abacavir.

### Treatment

When an offending agent is identified, its use should be discontinued. If a child is taking several drugs and the physician is uncertain of the offending agent, it is recommended to discontinue all nonessential medications. Whenever possible, any remaining possible offenders should be changed to alternative agents.

Therapy is directed toward the symptoms, with antihistamines used most commonly to alleviate pruritus. Topical agents are usually confined to moisturizers, which are most helpful during the desquamative phase of the reaction. Although topical steroids may be of some value in controlling pruritus, systemic steroids are rarely required.

### Complications

Most common exanthematous drug eruptions are without significant complications. However, continuing the use of the offending agent can result in 2 types of consequences—cutaneous and renal. When large areas of skin are inflamed, peripheral vasodilation can result in increased transepidermal water loss. This may become problematic in a critically ill child; however, it is usually well tolerated by most children. Most exanthematous drug eruptions heal without scarring. In children with dark-pigmented skin, postinflammatory hyperpigmentation or hypopigmentation may develop, but will fade over time. The renal risk is that of allergic interstitial nephritis, an uncommon development that is usually associated with penicillins and cephalosporins and only rarely with other drugs.

### Course

Drug eruptions gradually clear after the offending agent is discontinued, usually over 1 to 2 weeks. The rash may seem to worsen for several days after the offending agent has been stopped. The lesions then may darken to a tan or brown color and eventually fade. Although in some cases a drug eruption will clear even when use of the offending agent is continued, this should be avoided if an alternative agent is available. With exanthematous eruptions, if a responsible drug is identified, the reaction should be documented in the medical record. If there is doubt that a reaction reflects a true drug allergy, consultation with an allergist for further evaluation and possible oral challenge testing should be considered. Although an oral challenge is helpful in predicting immunoglobulin E (IgE)-mediated reactions, it is not helpful in predicting exanthematous ones. Very rarely, severe allergic reactions requiring hospitalization have occurred with

repeat drug challenges. Therefore, it is wise for drug challenges to take place in a controlled setting under the direction of an allergist.

## URTICARIA (HIVES)

### Etiology

Drug-induced hives can be mediated by either an immediate immunologic allergy (IgE- or immune-complex-dependent) or delayed nonimmunologic mechanisms. Immediate reactions are more common than delayed reactions. Drugs that induce urticaria by the nonimmunologic mechanism do not need previous sensitization, as they act as direct mediators for mast cell degranulation. Such medications include codeine, opiates, amphetamines, and radiocontrast media.

Conversely, drugs that are immunologically mediated require a period of sensitization. Once sensitization occurs, a type I hypersensitivity-mediated urticaria can develop within minutes following exposure. The most common offending agents are  $\beta$ -lactam antibiotics. Good management of urticaria depends on an understanding of the triggers and aggravating factors in addition to appropriate treatment options.

### History

The physician should obtain a history regarding timing of rash onset to drug, previous exposure to the drug, timing of discontinuation or decrease in symptoms upon removal of the drug, and specific symptoms and characterization of the rash (itching, migration of hives, associated bruising, associated angioedema). Over-the-counter medications and supplements should also be included in the history. It is important that physicians obtain a good history pertaining to the urticarial reaction as soon as possible, because often parents will not recall the details of the reaction once their child is referred to a specialist.

Many children and their parents tend to consider over-the-counter medications unimportant. Nonsteroidal anti-inflammatory drugs (NSAIDs) cause hives in some children and can aggravate them in those who have urticaria, regardless of its cause. Aspirin can cause hives, but is not widely used in children because of the possible risk of Reye syndrome.

A history of associated symptoms also may be important. Itching is almost a universal finding. Urticaria may be seen in combination with angioedema in 40% of cases. While urticaria rarely progresses to anaphylaxis, a combination of acute urticaria, angioedema, and extracutaneous symptoms (wheezing and cough) suggests anaphylaxis and necessitates immediate medical attention.

### Physical Findings

Hives usually appear as pink, edematous papules and plaques that are most often scattered, but can be generalized and even confluent. By definition, an individual hive is transient, lasting less than 48 hours, although new hives may develop continuously. Hives often assume geographic shapes, such as arcuate or annular. They can have pale or dusky centers and dark pink borders. Large or “giant” hives that are polycyclic with ecchymotic centers from vasoconstriction can be confused with EM and are termed “urticaria

multiforme” (UM) (Figure 245-1). This type of urticaria is more common in infants and preschoolers. It usually occurs acutely, often precipitated by a viral infection, immunizations, or recent antibiotic use. Urticaria in serum sickness reactions is commonly seen in conjunction with arthralgias, localized edema, fever, and lymphadenopathy.

### Differential Diagnosis

The differential diagnosis of urticaria may be approached in 2 ways—from the intrinsic causes of hives, and from consideration of the cause of lesions sometimes mistaken as hives. In children, the most common causes of acute urticaria are infection, drugs, and food allergies. Less often, physical modalities (eg, cold, pressure, or sunlight) and emotions can cause hives. Often, the precise cause remains elusive.

Urticaria multiforme should be considered on the differential diagnosis of acute urticaria. This benign hypersensitivity reaction is pathogenically similar to urticaria, but morphologically distinct. Usually following a viral infection, UM presents as polycyclic to annular urticarial plaques with a dusky center. They are commonly mistaken clinically for EM and serum sickness-like reactions. Unlike EM, the lesions of UM may have a dusky center, but are not targetoid (ie, they do not have a central necrotic or bullous component). Individual lesions in UM are transient, lasting 24 to 48 hours, while the lesions of EM are fixed

**Figure 245-1** Urticaria multiforme.

and can last for days to weeks. Children with UM may have edema of the face or extremities, but this is not usually seen with EM. Serum sickness–like reactions can mimic UM with polycyclic hives and localized edema, but those children also can have arthralgias, myalgias, and lymphadenopathy. Fever is usually higher than that seen in UM. A serpiginous band of erythema may be seen along the sides of the digits and along hands and feet. Drugs, especially antibiotics, are often the cause of serum sickness–like reactions. The cephalosporins have been documented to cause a serum sickness–like reaction in children.

Table 245-1 outlines clinical features of UM, EM, and serum sickness–like reactions.

Additionally, the individual lesions in juvenile rheumatoid arthritis behave similarly to hives in that they are transient, but differ in size (only 2–3 mm), color (typically salmon), and timing (usually appearing with fever spikes).

### Laboratory Studies

As with other drug eruptions, drug-induced hives may be accompanied by eosinophilia. To evaluate for hepatitis, the physician should check liver enzymes in children who have hives and fever. However, in afebrile children, laboratory tests are rarely helpful in eliciting a cause, and they are of no help in implicating a specific drug.

### Treatment

Use of any suspected medication should be discontinued. Symptomatic therapy is usually achieved with second generation H1 antihistamines, as they are well tolerated by children and have a decreased side-effect profile. It is recommended to schedule these medications, rather than dosing as needed. The safe maximum dose should be reached for 1 medication before adding additional oral antihistamines. If symptoms remain uncontrolled, the physician can decide, in a step-wise fashion, to add additional medications, including a second-generation H1 antihistamine, H2 antihistamine, leukotriene receptor antagonist, or first-generation antihistamine.

As with common urticaria, the lesions and pruritus of UM respond well to antihistamines and tend to resolve within a 1 to 2 weeks. Short courses of oral steroids may be used if antihistamines alone are unsuccessful.

### Complications

In rare cases, acute urticaria can be accompanied by anaphylactic reactions that require more immediate therapy; however, hives are usually more of a nuisance than a morbid threat. (See Chapter 350, Anaphylaxis.)

### Course

Acute drug-induced urticaria that is IgE mediated usually clears within 24 to 48 hours after the offending agent is discontinued. Once the agent is identified, the drug and members within that drug class should be avoided until further evaluation by an allergist. Skin-prick testing is available for penicillin and, if applicable, should be performed prior to any oral challenge with the drug so as to avoid a possible anaphylactic reaction.

## DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS/DRUG-INDUCED HYPERSENSITIVITY SYNDROME

Drug rash with eosinophilia and systemic symptoms is characterized by the clinical triad of fever, rash, and internal organ involvement (most commonly hepatitis, nephritis, pneumonitis, or myocarditis) that occurs within 2 to 6 weeks of initiation of the medication. Drug rash with eosinophilia and systemic symptoms is associated with the use of aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbital), lamotrigine, NSAIDs, sulfonamides, minocycline, azathioprine, metronidazole and allopurinol. Cross-reactivity with structurally related drugs is common. The incidence of DRESS with anticonvulsants is estimated at 1 in 10,000 exposures. There is some evidence to suggest that reactivation of certain viruses, such as human herpesviruses 6 and 7, cytomegalovirus, and Epstein-Barr virus, may be involved in the spectrum of multisystem

**Table 245-1**

**Distinguishing Features of Giant Urticaria, Erythema Multiforme, and Serum Sickness–like Reactions**

	GIANT URTICARIA	ERYTHEMA MULTIFORME	SERUM SICKNESS–LIKE REACTIONS
Duration of lesions	<24 hours	Days to weeks	Days to weeks
Location	Trunk, extremities, face	Palms, soles	Trunk, extremities, feet
Fixed lesions	No	Yes	Yes
Mucous membrane involvement	Oral edema common, no erosions or blisters	Erosions and blisters may be present	Oral edema common, no erosions or blisters
Facial or acral edema	Yes	No	Yes
Associated symptoms	Pruritus	Pruritus, burning	Lymphadenopathy, arthralgia, myalgia
Common triggers	Antibiotics, immunizations, viral illnesses	Herpes simplex virus, mycoplasma	Antibiotics

Adapted from Shah KN, Honig PJ, Yan AC. "Urticaria multiforme": a case series and review of acute annular urticarial hypersensitivity syndromes in children. *Pediatrics*. 2007;119(5):e1177–e1783.

reactions in DRESS. Reactions typically occur 1 to 8 weeks into drug therapy. The long latency period for development of symptoms may represent the dynamic interplay of several factors to result in clinical disease. It is postulated that the inability to clear reactive drug products, combined with impaired defenses, such as viral or nutritional, results in susceptible individuals developing DRESS.

Clinical manifestations include fever early in the course; diffuse macules, papules, or pustules that can progress to an exfoliative dermatitis mimicking SJS or TEN; eosinophilia; atypical lymphocytosis; and abnormal liver function test results. The severity of the skin involvement does not correlate with the extent of internal organ involvement.

Treatment consists of immediate withdrawal of all suspected medications, followed by supportive care of symptoms. Recent studies demonstrated good cutaneous response to topical corticosteroids in the absence of life-threatening organ involvement. Systemic corticosteroids are generally used in the more severe cases involving significant exfoliative dermatitis, pneumonitis, or hepatitis. Systemic steroids have been used concomitantly with intravenous immunoglobulin (IVIG), but IVIG as a monotherapy may result in increased morbidity and mortality. Case reports have demonstrated use of IVIG as an adjuvant agent in severe steroid-dependent DRESS. There are no large controlled studies showing statistical benefit of a particular treatment. Children with a history of DRESS should be followed for possible late manifestations, including recurrence of symptoms as well as development of hypothyroidism and type 1 diabetes mellitus.

### ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

Acute generalized exanthematous pustulosis is characterized by the sudden onset of fever and multiple nonfollicular, subcorneal pustules over widespread erythema. The pustules are sterile and may clinically resemble pustular psoriasis. They affect the trunk and intertriginous areas, but also can involve the face. About one-half of affected children may have facial edema or purpura involving the legs. This is one of the neutrophilic dermatoses; neutrophil-activating cytokines may be responsible for the increase in neutrophils in the blood and skin seen in this disorder. Acute generalized exanthematous pustulosis is relatively uncommon in the pediatric population. Drugs are often the trigger in adults, while, in children, a viral infection (Coxsackie B4 virus, Epstein-Barr virus) or recent vaccination is more likely than antibiotics to be the cause of AGEP. Resolution usually occurs 1 to 2 weeks following discontinuation of a suspected drug. Spontaneous resolution occurs when no medication is implicated. In both situations, fine desquamation is noted as the lesions clear.

### ERYTHEMA MULTIFORME

Erythema multiforme is an acute, self-limited eruption of symmetrical, erythematous macules and papules that can evolve into target lesions (Figure 245-2). It was first described by Ferdinand von Hebra in 1860

**Figure 245-2** Erythema multiforme.

and was later divided into minor and major forms (the major form being synonymous with SJS). However, according to current thinking, EM is best viewed as a separate entity from SJS and TEN despite some clinical and histologic similarities.

#### Etiology

In children and adults, EM most often occurs in association with recurrent herpes simplex virus (HSV) types I and II. Circulating immune complexes have been detected in patients who have EM, a finding consistent with the concept that this distinctive cutaneous disorder is an immunologic reaction. Other infectious agents that are rarely implicated in EM include histoplasma capsulatum and viruses, possibly Epstein-Barr virus. Many reported cases of presumed EM, ascribed to innumerable causes, were more likely UM.

#### History

Several factors are implicated in the development of EM, which include infections, medications, autoimmune disease, malignancy, and immunizations. Infections represent approximately 90% of all cases, and the most common infectious agent is HSV. Characteristic EM lesions are noted a few days to 2 weeks following HSV orolabial or genital infections, usually preceded by a prodrome of malaise, fever, and myalgias.

#### Physical Findings

As the name suggests, EM is characterized by a variety of lesions, including erythematous plaques,

blisters, and targetoid lesions. Hives are sometimes confused with target lesions. The difference is that a hive has only 2 color zones—a central pale area surrounded by an erythematous halo. The criteria for a target lesion require 3 zones—a central dark area or blister, surrounded by a pale zone, surrounded by a peripheral rim of erythema. True target lesions are diagnostic for EM. They are seen more often on the palms and soles, but may occur anywhere. Typically, EM is a strikingly symmetrical eruption that most often favors the dorsal hands and forearms. Other areas that are also often involved include the neck, face, and trunk. Lesions can be quite numerous, often exceeding 100 in number, and may appear grouped on the elbows or knees. The Koebner phenomenon can be observed—after cutaneous trauma has occurred, target lesions may appear in the affected areas. Mild, discrete, oral erosions occur in more than one-half of children, but are usually few in number and can be relatively asymptomatic.

### Differential Diagnosis

The skin reactions most commonly considered in the differential diagnosis are UM, serum sickness-like reaction, subacute cutaneous lupus erythematosus, viral exanthems, vasculitis, staphylococcal scalded skin syndrome (SSSS), and other blistering eruptions. Individual hives last fewer than 48 hours, while the lesions in EM persist much longer. Viral exanthems are usually monomorphous and tend to be less red, more confluent, and more centrally distributed than the lesions of EM. Purpura is the distinguishing feature of vasculitic lesions. Because it can be triggered by significant sun exposure, recurrent EM caused by HSV also can be mistaken for the photosensitive disorders polymorphous light eruption and juvenile spring eruption.

### Laboratory Studies

For herpes simplex disease, if the responsible vesicular lesion is still present, then its base can be scraped for HSV direct fluorescent antibody, or its fluid can be cultured for herpesvirus or examined for multinucleated giant cells (Tzanck preparation). Otherwise, laboratory evaluation usually is not helpful, although a leukocytosis can be seen.

When the diagnosis is in doubt, a skin biopsy can be helpful in excluding conditions that mimic EM, such as lupus erythematosus or vasculitis.

### Treatment

No convincing evidence has been found that medical therapy favorably alters the course of EM. Treating a precipitating infection seems appropriate, even though no proof exists that it alters the course of the skin reaction. Acyclovir begun after the onset of EM has not proven to be effective. Symptomatic treatment can be helpful—antihistamines may reduce the sensation of stinging and burning, and antacid suspensions applied topically may alleviate oral ulcers.

### Course

Erythema multiforme is a self-limited condition with resolution of symptoms usually within 4 weeks. Erythema multiforme recurs in 10% to 20% of children,

and recurrence is particularly common in patients with milder disease that is precipitated by recurrent HSV infection. Children with frequently recurring EM caused by HSV may be good candidates for prophylactic acyclovir for 6 to 12 months.

## STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Although previously thought to be more severe variants of EM, SJS and TEN are best viewed as separate entities. Stevens-Johnson syndrome and toxic epidermal necrolysis represent a continuous spectrum of a more severe process involving cell-mediated cytotoxic reactions aimed at epidermal cells. The process begins acutely with widespread skin lesions and mucocutaneous necrosis involving 2 or more mucosal sites, including conjunctiva, oral mucosa, the upper and lower gastrointestinal tract, and genital or anal mucosa. Stevens-Johnson syndrome produces more focal skin necrosis, with extensive areas of epidermal necrosis and resulting denudation occurring in TEN. The diagnosis of SJS is given when the child has less than 10% body surface area (BSA) involved. With 10% to 30% involvement, SJS/TEN overlap is used, and TEN is the diagnosis when more than 30% of BSA affected.

The current models of the pathophysiology of SJS/TEN involve widespread keratinocyte cell death in response to inappropriate immune activation caused by certain drugs, their metabolites, or infectious agents. Many soluble mediators of epidermal apoptosis and necrosis have been implicated, including Fas ligand, perforin, granzyme B, granulysin, interferon- $\alpha$ , and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ). Intracellular damage by reactive oxygen species formed in keratinocytes may precede the pro-apoptotic pathways. A domino-like effect with dying cells inducing further cytokine responses may amplify the process, resulting in widespread blister formation and denudation.

### Etiology

Medications are the most common cause of SJS and TEN. Antibiotics (mainly sulfonamides and less often penicillins, clindamycin, and quinolones), anticonvulsants (eg, phenobarbital, phenytoin, carbamazepine, and lamotrigine), oxicam-type NSAIDs, and allopurinol are implicated in about half of children. The TNF- $\alpha$  inhibitors were recently implicated as well as non-nucleoside reverse transcriptase inhibitors. A strong association exists with the genotype HLA-B\*1502 in Asians, especially people of Han Chinese ethnicity, and the development of SJS/TEN after exposure to carbamazepine. First-degree relatives of index cases have up to a 25% increased risk of developing SJS/TEN if exposed to a drug in that class. The FDA now recommends genetic screening for the HLA-B\*1502 allele in all individuals requiring carbamazepine if their ancestry puts them at risk. Testing for the HLA-B\*5701 genotype prior to therapy with the non-nucleotide reverse transcriptase inhibitor abacavir can determine if children would be at risk for SJS/TEN. In the future, perhaps more pretreatment genetic testing will be available for other classes of drugs to predict patient responses and thereby avoid a severe drug hypersensitivity reaction.

Infections, particularly from *Mycoplasma pneumoniae*, are the cause in about 30% of children. Many other infectious agents are reported to cause SJS/TEN, including viruses (Coxsackie, enteroviruses, influenza, mumps, hepatitis), bacteria (Group A *Streptococcus*, rickettsia, diphtheria, brucella, tularemia, typhoid, and Lymphogranuloma venereum), fungi (coccidia, histoplasma), and protozoa (malaria and trichomonas).

*Mycoplasma pneumoniae*-associated mucocutaneous disease is emerging as an entity distinct from EM, SJS, and TEN. Formerly known as “incomplete Stevens-Johnson syndrome,” this disease most commonly affects young males and presents with prominent mucositis and sparse cutaneous involvement. Cases have been treated successfully with oral antibiotic therapy and, occasionally, with IVIG. A few case reports show that IVIG is an effective second-line therapy in cases recalcitrant to oral antibiotics.

### History

Stevens-Johnson syndrome and TEN are usually preceded by a prodrome of up to 2 weeks of influenza-like symptoms followed by the abrupt onset of skin eruption. When drug related, the eruption typically begins 7 to 28 days after the causative drug is initiated. Drugs with longer half-lives are more likely to portend a worse prognosis than those with short half-lives, regardless of the structural similarity.

### Physical Findings

The eruption of SJS (Figure 245-3) and TEN (Figure 245-4) is initially macular or morbilliform, tender, dusky, and erythematous, with a widespread distribution. The skin sloughing occurs easily with minor friction (positive Nikolsky sign). Lesions gradually coalesce, and flaccid bullae develop that can extend

**Figure 245-3** Stevens-Johnson syndrome.

**Figure 245-4** Toxic epidermal necrosis.

laterally with central pressure (Asboe-Hansen sign). The bullae easily rupture and detach, leaving necrotic sheets of epidermis with a moist, bright red base. Mucosal erosions are seen in 90% of children and usually involve more than 2 mucosal sites. Thick, hemorrhagic crusts may appear on the lips. This process can progress for up to a week and is followed by re-epithelialization, which can take several weeks.

Constitutional symptoms also occur, especially in TEN. Systemic symptoms include fever, lymphadenopathy, hepatitis, and cytopenias. The epithelium of the respiratory tract is involved in 25% of cases, so management in an intensive-care setting is optimal. Additionally, gastrointestinal lesions may also occur, resulting in esophagitis and, less commonly, hemorrhagic diarrhea.

### Differential Diagnosis

The skin in SSSS is diffusely red and tender and also exhibits a Nikolsky sign. A skin biopsy helps distinguish SSSS from SJS. Histologically, the level of the blister is intraepidermal in SSSS, whereas the blister is subepidermal in SJS and TEN.

### Laboratory Findings

A chest radiograph is appropriate to screen for pulmonary involvement, including that caused by *M pneumoniae* infection, which can be confirmed further by cold agglutinins and acute and convalescent titers of immunoglobulin M antibodies to *Mycoplasma*. A complete blood cell count may show leukocytosis, and urinalysis may show hematuria or proteinuria.

Recent studies identified genetic variants associated with phenytoin-related cutaneous adverse reactions.

### Treatment

Any drug suspected of causing the reaction should be discontinued immediately, as early removal of an offending drug has improved survival. Early transfer of the patient to an intensive care unit that can manage children with severe skin burns also improves the ultimate outcome. Children with TEN can experience significant transepidermal fluid loss with associated electrolyte imbalance as well as respiratory, nutrition, and pain issues. Any underlying infection should be treated, and secondary infection should be prevented if possible. Patients who have severe oral involvement may be unable to eat and drink. Fluid replacement poses a unique challenge for children with SJS and TEN—unlike burn patients, the surface area involved in SJS and TEN may change, thus altering their fluid requirements. Fluid intake may need frequent adjustments to maintain constant urine output while avoiding fluid overload, which can lead to pulmonary edema, acute respiratory distress syndrome, and death. In fact, some experts recommend inserting a nasogastric tube on admission to maximize oral intake and decrease the need for intravenous fluids or parenteral nutrition, thus decreasing risk of fluid overload should the child's course become more complicated. In addition, parenteral nutrition requires a central venous line, with the attendant risks of sepsis and other line-associated complications. Local therapy with antiseptics and dressings may help prevent secondary

infection, and children who have severe involvement may require treatments similar to those for burn patients. In particular, silver nitrate-impregnated or newer biosynthetic or biologic dressings have been particularly helpful without causing further epidermal detachment on removal. Systemic analgesics are used for pain. Topical anesthetics may be used intraorally to provide temporary relief for children who have painful mouth lesions. Magic swizzle, containing 1 part each of diphenhydramine hydrochloride elixir, aluminum and magnesium hydroxide, and lidocaine viscous 2%, is one such agent. The physician should be mindful of the potential systemic effects of lidocaine when ordering this agent for young children.

The use of systemic steroids is controversial, because historically they were related to longer hospitalizations for sepsis and poor wound healing. However, more recent large retrospective studies found no increase in mortality with systemic steroid treatments in SJS and TEN in the past 15 years. Steroids alone were reported to be effective in SJS. Current studies are looking at the use of high-dose steroids very early in the course before significant denudation occurs, but well-controlled prospective studies are needed.

Intravenous immunoglobulin may hasten recovery from this disorder by blocking the mediators of the apoptosis cascade that leads to epidermal destruction. Intravenous immunoglobulin has been effective for SJS/TEN in children. Doses of 2 to 3 g/kg given early in the course lead to more rapid cessation of epidermal detachment and lower mortality. There are reports that systemic steroids given with IVIG may result in better outcomes in TEN and SJS/TEN overlap syndrome. Steroids and IVIG have been shown to improve the outcome in SJS and TEN, although well-controlled prospective studies are needed to determine optimal management.

### Course and Complications

The course of the disease can last as long as 4 to 6 weeks in children with severe involvement. Oral mucous membrane involvement can produce painful erosions, restricting intake and resulting in dehydration. Similar lesions in the genital mucous membranes can cause dysuria and urinary retention. Early ophthalmic evaluation is helpful since conjunctival involvement is common and can be severe. Internal organs are affected less often. Toxic epidermal necrosis in particular can affect the respiratory and gastrointestinal tracts. Respiratory involvement can lead to patchy pulmonary disease, bronchiolitis obliterans, and respiratory failure. Esophageal involvement can lead to dysphagia, malnutrition, and strictures. Involvement of the small intestine can lead to abdominal pain and diarrhea.

Long-term complications can be seen in up to 50% of children, with the skin and eyes most commonly affected. Postinflammatory hyper- or hypopigmentation is common. Even scarring can occur, depending on the depth of skin detachment. Nail changes are seen frequently and include Beau's lines, onychomadesis (nail shedding) and, occasionally, nail matrix scarring with permanent nail dystrophy. Xerostomia can result from SJS or TEN and, rarely, a Sjögren syndrome-like

**Table 245-2** Severity-of-Illness Score for Toxic Epidermal Necrolysis (SCORTEN)

SCORTEN PARAMETER	INDIVIDUAL SCORE	SCORTEN (SUM OF INDIVIDUAL SCORES)	PREDICTED MORTALITY (%)
Age >40 years	Yes = 1, No = 0	0–1	3.2
Malignancy	Yes = 1, No = 0	2	12.1
Tachycardia (>120/min)	Yes = 1, No = 0	3	35.8
Initial surface of epidermal detachment >10%	Yes = 1, No = 0	4	58.3
Serum urea >10 mmol/L (28 mg/dL)	Yes = 1, No = 0	>5	90
Serum glucose >14 mmol/L (252 mg/dL)	Yes = 1, No = 0	—	—
Serum bicarbonate <20 mmol/L	Yes = 1, No = 0	—	—

Derived from Bastuji-Garin S, Fouchard N, Bertocchi M, Roujeau JC, Revuz J, Wolkenstein P. SCORTEN: a severity-of-illness score for toxic epidermal necrolysis. *J Invest Dermatol.* 2000;115(2):149–153.

exocrine insufficiency can occur, especially with pancreatic dysfunction. Conjunctivitis can produce residual ophthalmic complications, including keratitis sicca, corneal ulceration or scarring, permanent visual impairment, and occasionally neovascularization and blindness. Newer techniques to minimize eye sequelae include amniotic membrane grafting early in the course of the disease before severe corneal damage occurs.

The risk of death is less in SJS than in TEN; death occurs secondary to extensive loss of skin integrity or complications from involvement of other organ systems. Mortality rates as high as 30% in TEN have been reported, but the mortality rate is around 7.5% in children. A severity-of-illness score for TEN (SCORTEN) was developed in which 7 factors are used to predict mortality (Table 245-2).

Early diagnosis and management of SJS and TEN with referral to a tertiary care center may lessen morbidity and mortality and improve the outcome of the unfortunate child who develops this disease process.

#### WHEN TO REFER

- Recurrent erythema multiforme
- Serum sickness-like reaction
- Drug hypersensitivity reactions with multiorgan involvement
- Unclear diagnosis

#### WHEN TO ADMIT

- Drug rash with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome
- Acute generalized exanthematous pustulosis
- Stevens-Johnson syndrome
- Toxic epidermal necrolysis
- *M. pneumoniae*-associated mucositis

### TOOLS FOR PRACTICE

### Chapter 246

## DRUG INTERACTIONS AND ADVERSE EFFECTS

Gitte Larsen, MD, MPH; Jared Cash, BS, PharmD

Adverse medication effects and drug interactions, condensed into the term *adverse drug reaction* (or ADR), may occur despite the best of intentions. Before administering a medication to a patient, it is essential to verify the “5 rights”—right patient, right medication, right time, right dose, and right route. However, even when all the 5 rights have been observed, a potentially life-threatening ADR may still occur. An ADR is implicitly caused by the interaction between the drug or drugs and patient-specific characteristics, some of which may be unknown prior to the medication administration.

### DEFINITIONS

The definition of an ADR is “an appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product, which

predicts hazard from future administration and warrants prevention or specific treatment, or alteration of the dosage regimen, or withdrawal of the product.” In an ADR, there is a causal link between the medication and the adverse event, and an imperative to determine the link by investigating the time relationship, pathophysiology of the drug, competing causes, and response of the patient to removal or reduction in the dose. Examples of such ADR scenarios include the occurrence of hypokalemia with the use of furosemide, gastrointestinal bleeding with the use of ibuprofen, or pancreatitis with the use of prednisone.

## EPIDEMIOLOGY

Adverse drug reactions are not uncommon occurrences during patient therapy, depending upon factors such as patient pharmacogenomics, the disease being treated, and medications being used, with 5% ADR occurrence for inpatients, and as high as 20% for outpatients, and an increasing risk for patients taking more than 4 drugs. In general, children are at approximately the same risk of ADRs as adults, and, in some cases, may be at higher risk. One systematic review of pediatric ADRs causing hospital admissions for children identified a rate of 0.4% to 10.3% (pooled estimate of 2.9%). In one pediatric study, a drug-drug interaction as a cause for hospital admission occurred rarely. In an international review of prospective, pediatric ADR studies, the skin and gastrointestinal system were most commonly involved, with an incidence of 1.5% to 19.9% among hospitalized children.

Adverse drug reactions generally occur by either a predictable, but excessive, pharmacologic effect caused by an increase in drug concentration or effect (type A), or by an unpredictable toxic or immunologic (eg, allergy, anaphylaxis) response (type B). A classification system of ADRs, evolving from the 2 categories of types A and B was initially proposed by Rawlins and Thompson, evolving from the 2 categories of types A and B, to 9 categories based on the known pharmacology and dose dependence of effects, further modified to include dose relatedness, timing, and patient susceptibility. For example, additional categories include type C (dose and time dependent [chronic] reactions), type D (delayed reactions), type E (withdrawal reactions), and type F (failure of therapy). Risks for ADR include previous adverse reaction to another drug, polypharmacy, prematurity, reduction in renal or hepatic function, larger medication dose, gender, and certain genetic polymorphisms. In the largest prospective, observational study of ADRs of all pediatric medical and surgical admissions, ADR risk factors included increasing age, oncologic disease, and number of medications taken. A gender predilection was not identified. The main classes of implicated drugs included opioid analgesics and anesthetic agents.

Pharmacogenomics, the study of the variability of the expression of individual genes relevant to the drug response at a cellular, individual, or population level, affects both the pharmacokinetics (absorption, distribution, metabolism, excretion) and pharmacodynamics of a drug. Genetic variations may provide some explanation

for significant differences in drug metabolism that can lead to toxicity and harm. There is significant potential through genetic testing to understand and predict not only medication efficacy, but also toxicity, with important differences attributable to gene expression changes during human development. For example, the death of a breastfed opioid-intoxicated neonate because of his mother's intake of prescription codeine-acetaminophen for episiotomy pain was later identified with the CYP2D6 ultra-rapid metabolizer genotype. The frequency of this genotype ranges from 1% in Finland and Denmark to 10% in Greece and Portugal and 29% in Ethiopia, and this genotype is associated with narcotic poisoning through otherwise routine dosing and even with secondary administration in the case of a breast-feeding infant. The pediatric fields of oncology, anticoagulation, psychiatry, and asthma in particular are advancing in the study of pharmacogenomics. To date there are more adult clinical applications, but the potential continues to be high. One comprehensive reference for pharmacogenetic data for individual drugs is located at [www.pharmgkb.org](http://www.pharmgkb.org).

## DRUG INTERACTION

Drug interaction is a generic term used when the efficacy or toxicity of a medication is changed by another medication or food. Several different mechanisms cause such interactions, and understanding them is critical for prevention, monitoring, and treatment. Drug-drug interactions can be further subdivided into pharmacodynamic, pharmacokinetic, and physical compatibility categories. Pharmacodynamic drug-drug interactions involve the basic pharmacologic effects of each medication opposing each other or having additive therapeutic or side effects. Examples include narcotic and benzodiazepine-potentiated sedative, as well as respiratory depressive, side effects. Pharmacokinetic drug-drug interactions encompass changes in the expected absorption, distribution, metabolism, or elimination caused by another medication (eg, liver enzyme induction or inhibition). The combination of amiodarone and digoxin or warfarin and trimethoprim-sulfamethoxazole are examples of pharmacokinetic interactions in which the combination results in toxicity of one or both agents, although each agent individually may not be an issue. Physical incompatibility is the third category of drug-drug interactions and involves medications that are combined in the same intravenous bag, syringe, or tubing, but for which there may be physical or chemical incompatibilities. Calcium and phosphate solubility is a common example.

Drug metabolism occurs in 2 phases. Phase I is characterized by modification reactions such that the parent drug is modified into a more hydrophilic compound. Phase II is characterized by conjugation such that the parent drug may be conjugated to a more polar, more readily excreted compound. Many drugs go through both phases, but some may only go through phase I or phase II. In some cases, the metabolite is metabolically active, or may be the source of toxicity, as with acetaminophen and its reactive metabolite N-acetyl-p-benzoquinone imine, associated with acute liver injury after an overdose. The most

well-studied and common phase I system is the cytochrome P450 (CYP), which includes more than 50 genes that encode for functional enzymes. There are several well-recognized drug–drug interactions because of the interaction between specific drugs and drug metabolizing enzymes (see Table 246-1).

Evaluating the potential for drug–drug interactions can be challenging. There are published resources in both print and electronic formats, but the poor agreement among them and difficulties with the practical integration of alerting functions into clinical information systems has generally yielded a plethora of insensitive, low-value drug–drug interaction alerts. These alerts from medication orders require a significant amount of vigilance to ensure that the most appropriate interactions are flagged. One particularly useful tool for tailoring interaction alerting is provided by the Office of the National Coordinator drug–drug interaction list; another is the list from the Leapfrog Computerized Physician Order Entry testing standard. However, interaction data is predominantly adult-based. Despite assumptions that pediatric data would be similar, analysis of the 24 drug pairs studied in both adults and pediatrics indicates that pediatric patients can experience a higher, similar, or lower level of drug–drug interaction compared to adults.

Drug–food interactions can also be subdivided into separate categories, such as absorption, allergies, antagonism, and nutritional deficiencies. Food, in general, may inhibit or improve a medication's absorption, although concern for this type of interaction should be reserved for narrow therapeutic medications, such as methotrexate, or for when clear clinical consequences have been identified, such as calcium-rich foods binding quinolones or dietary iron interfering with tetracycline absorption. A drug's effect may also be antagonized by the specific content of food, such as high vitamin K content and warfarin, or calcium and calcium antagonists. These antagonism interactions

are generally not contraindications, but should be considerations for patient counseling about moderation. Nutritional deficiencies are a type of drug–food interaction that deserves monitoring, usually in chronic care settings rather than for short courses. Examples include valproic acid and its antifolate effect, and oral steroids severely affecting vitamin D levels.

## APPROACH TO ADVERSE DRUG REACTIONS

Developing a systematic approach to a patient with a suspected ADR can clarify and identify the source. In the case of a skin reaction, categorize the primary lesion as exanthematous, urticarial, blistering, or pustular. By including the presence or absence of systemic signs, an initial clinical impression can be formed and a differential diagnosis generated. Recommended next steps are as follows: (1) Obtain a complete history of the drugs taken, including types, doses, and duration. This history should include over-the-counter medications and herbal and naturopathic compounds. (2) Obtain a detailed description of the symptoms and signs, including onset, localization, and evolution. (3) Perform an examination of skin and mucosal membranes. (4) Assess vital signs and laboratory parameters that suggest warning signs (eg, hypotension, fever, skin blisters or bullae, complete blood count for lymphopenia or thrombocytopenia, eosinophilia, liver transaminases, renal function panel). In the absence of a definitive diagnosis, defining the reaction as highly probable, probable, possible, unlikely or almost excluded can be helpful. To fulfill the criteria for a highly probable reaction, the following principles of causality should be met: temporal relationship, a recognized response to the suspected drug, improvement after drug withdrawal, and reaction on rechallenge. A probable reaction includes principles 1 to 3; a possible reaction requires only a temporal relationship.

## DOCUMENTATION AND COMMUNICATION

Recognition is a key first step when an ADR occurs, allowing measures to be taken to minimize the recurrence if possible. Data are often captured in nurse charting, but may be inappropriately minimized or trivialized as side effects of a drug and thought to be unavoidable. One example is pruritus with morphine, which may not be seen as serious and may, therefore, be labeled as a side effect; but following this assessment could lead to compounding reactions, risking delirium if diphenhydramine is added to the patient's medication profile. With recognition of the initial ADR, alternative narcotics could be chosen and such risks minimized.

Documenting ADRs in the medical record is also helpful in preventing subsequent harm to patients given the high likelihood for recurrence and the causal association between the medication and symptom occurrence. Life-threatening ADRs merit documentation (eg, trimethoprim/sulfamethoxazole-induced toxic epidermal necrolysis or Stevens-Johnson syndrome). A valuable strategy when documenting ADRs is to note the severity of the reaction, the causal association between the medication use and the event, and the dosing variables. Often inpatient records with details do not translate well into the outpatient arena. A commonly overlooked step is clear communication with the family about the ADR and its causality and implications, including sharing these findings with other practitioners involved with the patient.

## REPORTING TO THE US FOOD AND DRUG ADMINISTRATION

It is essential that ADRs associated with new drugs be reported, because drugs entering the market are tested on relatively few patients before being released, and serious ADRs that occur at a frequency of 1 case per 1,000 population or less are unlikely to be detected prior to drug approval. This is especially true in pediatrics, which makes reporting even more crucial. The US Food and Drug Administration (FDA) is interested in "any [unexpected] adverse drug experience that is not listed in the current labeling for the product." Reporting is done through the online FDA Adverse Event Reporting program, and drug and drug class safety warnings issued by the FDA are available at [www.fda.gov/Safety/MedWatch](http://www.fda.gov/Safety/MedWatch).

## Chapter 247 ENCOPRESIS

Barton D. Schmitt, MD

### DEFINITION

Encopresis (soiling) is the intentional or involuntary passage of feces into the clothing by children with a developmental age greater than 4 years. Any child with a developmental age greater than 3 years who is not toilet trained, however, should be evaluated. Without professional advice for this age range, many parents mistreat encopresis with coercion or punishment, and the condition worsens. Sometimes constipation has been overlooked.

Most children who have encopresis leak fecal material involuntarily from constipation or an impaction (retentive encopresis). Some children simply pass normal stools into their underwear rather than use the toilet (nonretentive encopresis). Retentive and nonretentive encopresis should be separated because the treatment for each type is radically different. The minor fecal staining that occurs when children do not wipe themselves adequately after using the toilet should not be mistaken for encopresis.

## PATHOPHYSIOLOGY

Retentive encopresis is associated with constipation (see Chapter 134, Constipation). The type of constipation that is associated with encopresis is usually a result of stool holding. Young children may postpone bowel movements because of pain or because they want to cooperate with toilet training. Understanding of retentive encopresis also depends on an understanding of the pathophysiologic features of fecal impaction, which occurs when constipation has gone unrelieved for approximately 1 week. By then, the rectum is so distended with stool that the sacrospinal defecation reflex is no longer energized, and the mass is so wide that voluntary effort alone cannot force it through the anal canal. Hence, an impaction is almost irreversible by natural events. The pressure of the impaction dilates the internal anal sphincter and makes it incompetent. Small amounts of the lower impaction are extruded intermittently through the external sphincter as a result of gravity, exercise, and relaxation.

Nonretentive encopresis in children who are developmentally normal is usually a result of behavioral problems around toilet training. Children with irritable bowel syndrome of childhood or other causes of chronic diarrhea (see Chapter 138, Diarrhea and Steatorrhea) can also have delays in toilet training. Children with cerebral palsy, spina bifida, or other neuromuscular problems can have difficulty toilet training despite normal cognitive development.

## INCIDENCE

Encopresis affects approximately 5% of 4-year-olds who have normal development. It affects 2% of kindergarten and first-grade students. If their child is not bowel trained, most parents seek help by age 3 or 4 years. Some children who have encopresis are not brought in for examination until 5 years of age, when their symptom interferes with school entry. Affected boys outnumber affected girls by a ratio of 3:1.

## DIFFERENTIAL DIAGNOSES

Most constipation of childhood is caused by stool holding either as an attempt to avoid the pain associated with passage or because the child is enmeshed in a control struggle with a parent. Retentive encopresis has an organic basis in fewer than 5% of encopretic children. Organic causes of constipation and retentive soiling often are noted on physical examination (Table 247-1).

Approximately 10% to 20% of children who are encopretic are not constipated. Frequently, preschoolers who are of this type are resisting bowel training deliberately. Most school-aged children who have this type are postponing bowel movements (BMs) (*waiting too long*) because they do not want to leave some enjoyable activity (eg, video games) or they do not want to use public toilets (eg, school bathrooms). Many of them have a difficult or strong-willed temperament that makes them prone to engage in control battles.

Many encopretic children (of either type) eventually develop secondary emotional problems unless treated appropriately. Encopresis can take a great toll in shame. The unpredictable nature of the symptom

**Table 247-1**

### Organic Causes of Constipation and Retentive Soiling

ENTITY	DIAGNOSTIC CLUE
Constipating medication	History positive
Constipating diet	History positive
Chronic anal fissure	Examination positive
Perianal cellulitis	Examination positive
Hypothyroidism	Linear growth delayed
Anal or rectal stenosis	Finger cannot enter rectum
Pelvic mass	Mass found on rectal examination (usually posteriorly)
Hirschsprung disease	Rectal ampulla repeatedly empty; rectum is tight

in retentive children causes constant fear of exposure. Many of these children are *scapegoated* at home, teased by peers, and ostracized at school. Having a child with encopresis is very embarrassing and stressful for most parents. It may cause them to overreact and become negative in their childrearing, further compounding the problem.

## EVALUATION

### History

A thorough history usually distinguishes between retentive and nonretentive encopresis (Table 247-2). The pediatrician asks about size and consistency of stools and soiling intervals. In the retentive form, leakage occurs many times a day or even continuously. Commonly, the pediatrician elicits a history of periodic pain or crying with BMs, blood on the toilet tissue, passage of a huge BM that clogs the toilet, or posturing that suggests deliberate holding back. By contrast, the child who has nonretentive soiling passes a BM of normal size and consistency into the underwear once or twice a day; no symptoms of constipation are exhibited.

The pediatrician should clarify early on whether the child is toilet trained. By definition, most are not. Previous toilet training methods, rewards, and punishment are important. Information about sitting on the toilet is essential (eg, how many times per day and if sitting is spontaneous or prompted by parents or teachers). Refusal to sit on the toilet means that treatment will be difficult. If the stool pattern is unknown, then sending the parent home with an encopresis diary to complete for the child can be most illuminating. Feedback from the school or child care provider may be needed. Enuresis is also present in many of the children with retentive encopresis. Other helpful parts of the history pertain to diet: The intake of milk products (especially cheese), fruits and vegetables, and fiber should be recorded.

### Physical Examination

The physical examination provides definitive information. In retentive soiling, an abdominal mass is usually palpable. Although the mass sometimes extends throughout the entire colon, it more commonly

**Table 247-2**      **Differentiation of Retentive Soiling From Nonretentive Soiling**

	RETENTIVE SOILING	NONRETENTIVE SOILING
<b>HISTORY</b>		
Symptoms of constipation	Yes	No
Soiling interval	Many times per day	Once per day
Soiling amount	Small	Normal
Soiling consistency	Loose	Normal
Previous need for laxatives, suppositories, or enemas	Yes	No
<b>EXAMINATION</b>		
Abdominal mass	Yes	No
Abdominal distention	Often	No
Anal canal	Sometimes full	Empty
Rectum	Packed	Normal

involves only the rectosigmoid area. The mass is midline, suprapubic, irregular, and movable. The mass can be missed if the rectus abdominis muscles are not relaxed. The backup of gas and stool can cause a protuberant abdomen. Inspection of the anus should be part of the routine evaluation of encopresis. The lumbosacral area should be examined for midline defects.

A digital rectal examination is needed when it is not clear whether or not the child is retentive (constipated). It is also needed in children with retentive encopresis who do not respond to standard management. It can be done with minimal pain and distress in most children. Overlooking this part of the evaluation can lead to an erroneous diagnosis. Inspection of the anal opening often reveals protruding fecal material in children who are deliberate stool holders. This is uncommon in children who want to release the stool. By definition, the rectum in impacted children is dilated and packed with wall-to-wall stool (often 6 to 10 cm across). The consistency of the impaction more commonly is similar to wet clay, rather than hard. By contrast, the child who has nonretentive soiling has normal abdominal examination findings, and the rectal vault contains either a stool of normal caliber or nothing if the child has evacuated recently. Hirschsprung disease also causes an empty rectum despite a history of stool retention, but stool may be expelled immediately on removal of the finger.

### Laboratory Studies

Children who are encopretic generally need no routine laboratory confirmation of this diagnosis. Because an impaction can cause partial bladder emptying and urine retention, a urinalysis for nitrite and pyuria may be helpful to screen for urinary tract infection, especially if any associated enuresis exists. Any abnormal perianal erythema should be cultured for group A *Streptococcus*. Occasionally, thyroid function tests are warranted, especially in children with short stature or other signs of hypothyroidism.

### Radiographic Findings

If the examiner cannot determine whether the patient is impacted (eg, severe obesity, abdominal fullness

but empty rectum), a postvoiding, supine abdominal radiograph can be helpful. Other indications include sexually abused children who might be emotionally traumatized by a rectal examination and those who refuse a rectal examination. A child who is impacted will demonstrate on radiograph a rectum and sigmoid colon grossly dilated with granular stool and increased stool in the transverse and descending colon, which normally is empty. A healthy child will have stool only in the ascending colon and the rectosigmoid area. Also, the stool will be of normal diameter. A barium enema is rarely indicated in children with encopresis or constipation. One exception is if Hirschsprung disease is suspected based on an empty rectum on repeated examinations. Also, children who have retentive soiling and experience repeated treatment failures may warrant a barium enema to ensure that a rare diagnosis (such as an extrinsic mass pressing on the lower sigmoid or rectum) has not been overlooked.

## MANAGEMENT OF RETENTIVE ENCOPRESIS

In recent years, the treatment of constipation has become more uniform. The need for chronic medications to allow the lower bowel adequate time to return to normal diameter and function has gained acceptance. Most children older than 5 years want to stay clean. However, they may not understand how to do so. Physicians should tell these children that they need to pass a stool every day. They need to keep their rectum empty. Physicians should help them understand that holding back BMs is the main cause of leaking or messing their pants. (Box 247-1 outlines the treatment of encopresis.)

### Initial Disimpaction

Unless the impaction is removed, the child will be unable to regain bowel control. The traditional rapid way to remove an impaction is to give a daily sodium phosphate enema for 2 or 3 days. Warn the parents that phosphate enemas given in excessive doses can cause serious side effects. Although rare, these include tetany, dehydration, arrhythmias, and even death.

**BOX 247-1 Treatment of Retentive Encopresis**

- *Bowel clean out:* hyperphosphate enemas (1 daily for 2 or 3 days) to remove impaction (*other option:* oral clean out using high-dose stool softeners)
- *Maintenance medication:* polyethylene glycol or mineral oil for 3 to 6 months to keep the stools soft and painless; senna laxatives added to regimen if stool softeners are not completely effective
- *Toilet habits:* sitting on the toilet for 10 minutes after meals
- *Diet:* nonconstipating high-fiber diet
- *Rewards:* give incentives for release of stools; base amount on size of stool
- *Stool output diary:* parents need to track daily stool output, both complete stools and small "accidents"; this information aids the pediatrician in adjusting medication dosage or prescribing another clean out
- *Referral:* refer treatment failures to mental health professional or gastrointestinal subspecialist
- *Pediatrician role after referral:* stay involved to prevent reimpaction

For children who are resistant to enemas or parents who are unable to give them, administering high-dose polyethylene glycol or mineral oil orally can also dislodge the impaction if the treatment is continued for approximately 3 or 4 days. During this time, the child must stay at home because the timing of the large release cannot be predicted. A combination of these 2 approaches, starting with polyethylene glycol or mineral oil orally and followed by enemas on day 3, may be useful. Occasionally, enemas have to be administered in the office or clinic.

Rarely, for severe impactions involving the entire colon, a child needs to be hospitalized for the clean out. The usual procedure is to give polyethylene glycol-electrolyte solution by nasogastric tube for 8 to 24 hours.

**Stool Softeners**

As soon as the impaction is eliminated, the long-term treatment of constipation should be administered orally. Mineral oil or polyethylene glycol is prescribed (Table 247-3). Lactulose is less effective. The goal is the passage of 1 or 2 normal-sized BMs per day. Stool softeners must be continued for 3 months because bowel diameter and tone require this amount of time to return to normal. If the child refuses to take straight mineral oil, then parents can consider a better-tasting (although more expensive) emulsified derivative of mineral oil.

**Laxatives**

Stool softeners are the first line of therapy for constipation. If stool softeners are not effective, then laxatives (bowel stimulants) to help the child keep the rectum empty should be added. Laxatives are usually needed for children who deliberately hold back BMs

or for those who have acquired megarectum and megacolon (for dose levels, see Table 247-3).

Undermedicating is the main cause of treatment failure and recurrences. If the child is not having a normal-sized BM daily, then the dose should be increased. Some children temporarily require doses that exceed the standard dose recommended by textbooks and the package insert. Many parents worry unnecessarily about laxative dependency. They should be reassured that children can be tapered off laxatives successfully, even after 6 months of taking them. All affected children need stool softeners or laxatives for at least 3 months, and many for 6 months or longer. Many parents are in a hurry to stop the medications; they should be told on the first visit that to achieve a cure, medications need to be continued until the child has gone at least 1 month without any soiling. The medications then can be tapered gradually over 2 months.

**Toilet Habits**

The child should sit on the toilet for 5 to 10 minutes once a day with a timer. The gastrocolic reflex, which takes effect 20 to 30 minutes after a meal (especially breakfast), can be used to advantage. Any treatment that neglects this opportune timing will likely fail.

Children who have been impacted for many months may have no urge to defecate. The defecation urge may not return until the rectum is kept empty for 1 to 2 weeks. Many parents do not understand this and need to be educated that the return of bowel control will be gradual. Other important tips to impart to children are to flex the hips to open the rectum, to use a footstool for leverage, and to apply some pressure to the abdomen while pushing down. If they have no BM for 24 hours, then these children need to sit on the toilet more often and longer each time. Soiling (leakage) also requires sitting on the toilet, followed by a cleanup.

Some preschoolers and toddlers adamantly refuse to sit on the toilet, holding back their stools when they are forced to do so. The overriding goal is to produce a BM daily or at least every other day. Passing it into the diaper is better than holding it in. In cases such as these, pediatricians and parents need to lower their expectations. The child can be told that the "poop wants to come out every day, and it needs your help." Going in the diaper is fine. Rather than putting the child back in diapers or Pull-Ups full time, the child should be given access to them when the need to release a stool exists. This approach prevents the child from regressing with bladder control.

**Nonconstipating High-Fiber Diet**

All constipated children need more fiber in their diet, as is found in foods such as popcorn, grains, fruits, and vegetables. However, diet therapy alone will cure only children who have mild constipation. The only foods that have been shown to be constipating are milk products. Identifying the 10% or so of children who have impaction and who are drinking great amounts of milk (>32 oz per day) is important. Milk intake can be limited to 16 oz per day in children older than 1 year. Fluid

**Table 247-3 Medications for Constipation**

MEDICATION	DOSAGE	COMMENTS
<b>STOOL SOFTENERS</b>		
Mineral oil	1–2 mL/kg/dose twice daily Adolescents: 60 mL/dose (max: 8 oz/day)	Do not use in children who have gastro-esophageal reflux or vomiting or who are not yet walking. Emulsified types (Petrogalar, Agoral plain, Kondremul) taste better. This is a prescription item.
Lactulose	0.5–1.0 mL/kg/dose twice daily Adolescents: 15 mL twice daily (max: 3 oz/day)	
Polyethylene glycol (MiraLAX)	0.5 g/kg/day Adolescents: 17 g/day	MiraLax is nonprescription item. Identical prescription version is call GlycoLax.
Milk of Magnesia	1–2 mL/kg/dose Adolescents: 30–60 mL	1 Milk of Magnesia tablet = 2.5 mL liquid
<b>STIMULANT LAXATIVE</b>		
Senokot (senna)	<5 yr: 1–2 tsp syrup/day >5 yr: 2–3 tsp syrup Adolescents: 1 tbsp/day (max: 2.5 tbsp or 8 tablets)	1 tablet = 3 mL granules = 5 mL syrup
Fletcher's Castoria	<5 yr: 1–2 tsp/day >5 yr: 2–3 tsp Adolescents: 2 tbsp max	—
Ex-Lax (senna)	>5 yr: 1 square/day Adolescents: 2 squares	Chewable squares
Dulcolax, 5-mg tablet	>5 yr: 5 mg/day >12 yr: 10 mg (2 tablets) Adolescents: 4 tablets max	Liquid form not available.
<b>RECTAL SUPPOSITORIES</b>		
Glycerin suppository	1 or 2 suppositories	
Dulcolax suppository 10 mg	>2 yr: 1 suppository	
<b>ENEMA FOR DISIMPACTION</b>		
Mineral oil enema	1–2 oz/20 lb of weight/day Adolescents: 4 oz	Squeeze-bottle size: 4.5 oz
Sodium phosphate enema (Fleet)	1 oz/20 lb of weight/day Adolescents: 4 oz (max: 8 oz)	Squeeze-bottle size: 2.25 oz children, 4.5 oz adult Caution: avoid enemas if <2 years old
<b>ORAL DISIMPACTION</b>		
Mineral oil	1 oz/yr of age/day Max: 8 oz/day	—
Polyethylene glycol (MiraLax)	0.5 gm/kg/dose 3 times daily Max: 25 g or 1½ capfuls 3 times daily	—

requirements for constipated children can be met with fruit juices, especially those that have a high sorbitol content, such as pear, peach, or prune juice. Sorbitol can increase the frequency of stools.

### Follow-Up Visits

All children who have impaction need follow-up approximately 1 week into treatment; more than 30% still will be impacted. The abdominal examination and underwear check should be repeated even if patients tell you that they are having normal BMs and no soiling. Children who have an impaction actually can keep themselves clean temporarily by making a strenuous effort at control and sitting on the toilet several times a day. If the history and abdominal examination leave

uncertainty, then a rectal examination should be performed.

If a child still is impacted at the follow-up examination, then a more detailed explanation of the disimpaction process is necessary. Some children need enemas in the office at this point.

### Backup Plan for Recurrence of Constipation or Encopresis

Backup plans are critical for preventing all-too-frequent relapses. If the child goes for longer than 48 hours without a normal-sized BM, then the parents should be instructed to increase the dose of stool softener or laxative. This approach is critical to prevent impaction from recurring.

If soiling occurs more than twice over a few days, then the child is at risk for recurring impaction. At this point, the parents should intervene vigorously by giving a double dose of laxative, a suppository, or an enema. Merely mentioning an enema sometimes results in the child sitting on the toilet and producing a BM. For older children who are cooperative about sitting on the toilet, sitting there for 10 minutes out of every hour will usually relieve an early impaction. Again, the family should be helped to realize that soiling always means that the rectum is full and the impaction is returning.

Failure of these primary care interventions is usually a result of rectal hyposensitivity and inability to relax the external anal sphincter. The former is caused by prolonged stretching of the rectum. The latter results from constant voluntary attempts to prevent stool leakage or pain. Both of these pathophysiologic states usually recede after stool impaction is permanently resolved with more aggressive interventions.

## MANAGEMENT OF NONRETENTIVE ENCOPRESIS

For children who simply postpone BMs, a simple admonition to “find a toilet whenever you feel rectal pressure” or “don’t make your body wait” usually removes the symptom. Most children with nonretentive encopresis, however, are resistant to toilet training, and they need more intensive intervention (Box 247-2).

### Medications

Stool softeners, laxatives, and enemas are not needed for cases of nonretentive encopresis.

### Reminders and Lectures

The parents should be reassured that nothing more can be taught to their child. The parents should be told to stop all reminders about using the toilet and let the child decide when he needs to go to the bathroom. By transferring the control to the child, power struggles will end. Children should neither be reminded to go to the bathroom nor be asked if they need to go. Reminders, inquiries, and lectures are a form of pressure, and pressure does not work. The parents should not threaten punishment. Many young children try to hold back all BMs to avoid punishment, such as being spanked or grounded for soiling. They are under the mistaken impression that not passing any BMs is the best way to avoid punishment. The parents should be told about the importance of not punishing their child for soiling. The child should be reassured that soiling will no longer incur punishment. Parents also need to try to deal with soiling and cleanups in a calm way.

### Incentives

Incentives for passing BMs into the toilet should be given and the parents should be reassured that this approach is how they can turn the tide. If the child passes a BM into the toilet, then the parents should give immediate positive feedback, such as praise, a

## BOX 247-2 Treatment of Nonretentive Encopresis

- Tell the child, “You are in charge of your body and your poop.”
- Stop all reminders, lectures, or punishments (ie, dismantle the power struggle).
- Give incentives for passing stools into the toilet.
- For soiling, insist on immediate cleanup.
- Medications are not needed.
- Refer treatment failures to a mental health professional.
- The role of the pediatrician after referral is to stay involved for ongoing health care.

hug, and a sticker. To achieve a breakthrough with some children who have never had a BM into a potty chair or toilet, the parent can offer major incentives, such as going out to their favorite restaurant, watching their favorite video, or getting treats. A star chart also helps many children stay focused on the goal of releasing stool into the potty chair or toilet. Incentives are also helpful in younger children who hold back BMs and resist sitting on the potty.

### Changing Soiled Underwear

Soiling should not be ignored. The parents’ only remaining assignment is to help the child change clothes when they become soiled. As soon as the parents notice that the child has messy pants, they should clean the child immediately. Changing should be made a neutral, timely interaction.

## PROGNOSIS

Pediatricians should be independently able to manage most children with constipation. The management of constipation with encopresis may be more difficult. If the retentive encopresis is caused by pain avoidance, primary care management can cure 95% of these children’s constipation. If the retentive encopresis is caused by a toilet-training battle or other control issues, the challenge is combining medical and behavioral management. The pediatrician may be able to cure 70% of these children independently. For the others, she will need to collaborate with a mental health professional. Levine studied 127 encopretic children of the retentive type managed by a developmental pediatrician. After 1 year, 51% were cured, and 27% had marked improvement.

Nonretentive encopresis is much easier to treat than retentive encopresis. These children have good results if the problem is recent and poor results if the problem is longstanding (>5 years). In mildly resistive children, primary care management can achieve a 90% to 95% cure rate if the right incentives are identified and implemented. Children who have severe resistance need early referral. Box 247-3 lists the reasons for referral of encopretic children to a mental health professional.

**BOX 247-3 When to Refer Encopresis to a Mental Health Professional**

- Refuses to sit on the toilet and is older than 4 years
- Refuses to take medications
- Refuses to give up stool holding
- Has nonretentive encopresis and is unresponsive to pediatric management
- Has nonretentive encopresis and is older than 8 years
- Deliberately passes stools on family possessions or at school (overt anger)
- Has stool smearing that is a recurrent problem
- Has major developmental disability and cannot be toilet trained
- Has oppositional-defiant disorder, depression, or other serious mental illness
- Has severely strained or angry parent-child relationship

Referrals to a pediatric gastrointestinal specialist are needed less often than referrals to a behavioral pediatrician or mental health professional. Appropriate referrals are children with repeated impaction, unresponsive constipation, or constipation of unknown etiology.

**SUMMARY**

The pediatrician plays a critical role in evaluating children with encopresis. Initial sorting of retentive (constipated) from nonretentive encopresis is critical because they require different management strategies. Placing nonretentive children on stool softeners is unnecessary and will increase stool leakage. Not recognizing retentive children and not placing them on appropriate medications means their problem will only become worse.

The pediatrician can treat many of these children successfully. Because encopresis causes psychological stress for both the child and the family, severe cases that do not respond to pediatric management require prompt referral. If a child with retentive encopresis is referred to a mental health professional, the pediatrician must also see the patient at regular intervals to titrate medications and prevent impaction.

**Chapter 248****ENTEROVIRUS AND EVOLVING INFECTIONS**

Dennis Cunningham, MD; Chokechai Rongkavilit, MD;  
Kanagasabai Udhayashankar, MD, MPH;  
Michelle L. Niescierenko, MD

**ENTEROVIRUS INFECTIONS**

Enteroviruses are members of the Picornaviridae family along with parechoviruses, and share a genus with rhinoviruses, coxsackieviruses, and polioviruses. All members of the genus *Enterovirus* have single-stranded RNA. Enteroviruses infect mammals. There are more than 110 subtypes of enteroviruses that can infect humans. A newer, more practical classification divides *Enterovirus* into 4 subtypes:

- Enterovirus A (25 viruses)
- Enterovirus B (61 viruses)
- Enterovirus C (23 viruses)
- Enterovirus D (5 viruses)

Enterovirus serotypes causing more severe disease include polioviruses (EV C), enterovirus 71 (EV A), and enterovirus 68 (EV D).

**Epidemiology**

In the United States, enteroviruses typically cause outbreaks in the late summer and early fall, but disease may occur at lower levels year round. In the tropics, *Enterovirus* infections occur year round. Children younger than 10 years have the highest incidence of *Enterovirus* infections. Humans shed enteroviruses in the feces for weeks after infection, and fecal-oral transmission is the predominant mode of transmission. Infection through the respiratory tract is possible and may be the predominant transmission mechanism for some individual viruses, such as enterovirus D68.

Certain enteroviruses have particularly significant epidemiologic importance. Polioviruses caused widespread outbreaks of disease, with a small percentage of infected patients developing acute flaccid paralysis. Currently enterovirus 68 infection is associated with an increased rate of respiratory illnesses requiring hospitalization. Enterovirus 71 is a major cause of disease in Asia. Coxsackievirus A24 and enterovirus 70 infections often lead to widespread hemorrhagic conjunctivitis outbreaks. Certain subtypes have a strong association with viral meningoencephalitis (echoviruses 13, 18, and 30). A recent study implicates enteroviruses as a trigger for type 1 diabetes mellitus.

A patient with a primary immunodeficiency has a higher risk for severe enterovirus infections. Patients with deficits in humoral immunity, particularly X-linked agammaglobulinemia, have the most severe illness and often develop chronic infections with high morbidity and mortality. Other immunodeficiencies associated with severe enterovirus infections include severe combined immunodeficiency, common variable immunodeficiency, and hyper-immunoglobulin M (IgM) syndrome.

### Symptoms

Enterovirus infection symptoms range from none to meningoencephalitis or a sepsis like presentation. Because most children with infections do not require medical care, the true incidence of enterovirus infections is unknown. Improved viral diagnostic testing for enteroviruses by polymerase chain reaction (PCR) means the diagnosis of infection is much easier. In one study, investigators identified *Enterovirus* species in 12.8% of all infants seen in a primary care setting during peak enterovirus season. Most infants, 80%, had asymptomatic disease. Those with symptoms presented with fever and lethargy. Approximately 50% of infants admitted with a fever of unknown origin have an enteroviral infection. Although most infants present with a nonspecific fever or meningoencephalitis, mortality is extremely low. These infants often present with fever, decreased oral intake, and fussiness. There is no evidence that enteroviral meningoencephalitis has long-term effects on central nervous system development later in life. Infants may present with a petechial rash. Rarely, infants with an enterovirus infection present with a sepsis like picture characterized by hepatic involvement and coagulopathy. Onset is very rapid, and the mortality rate reaches 24%. Circulatory collapse (shock) or hemorrhage causes most deaths. Infants may present with skin lesions such as petechiae and purpura, which may resemble purpura fulminans. An uncommon presentation in infants is myocarditis, which has a mortality rate greater than 70%.

Outside of the neonatal period, children often present with a fever and nonspecific symptoms. Children often present with gingivostomatitis, a febrile illness with vesicles and ulcers in the oropharynx or buccal mucosa. Symptoms may last for a week. Hand, foot, and mouth disease is a combination of oral lesions and vesicular lesions on the hands and feet, specifically the pulp of the fingers and toes. Coxsackievirus A16 is the most common cause of hand-foot-and-mouth disease in the United States. Widespread community

outbreaks of hemorrhagic conjunctivitis are associated with enterovirus 70 and coxsackievirus A24. Enteroviral meningoencephalitis presentations range from fever with a mild headache to changes in mental status.

In August 2014, 2 children's hospitals noted increased numbers of patients presenting with respiratory disease. The Centers for Disease Control and Prevention (CDC) identified enterovirus D68 in most of the children. At the time of publication, more than 43 states had confirmed cases of enterovirus D68 infections. Symptoms of enterovirus D68 infection range from a mild upper respiratory tract infection with cough, sneezing, and fever to a severe respiratory illness that may trigger severe wheezing and hypoxia. Treatment is supportive. Patients with respiratory enteroviral disease who have known reactive airway disease or asthma need to take controller medications as prescribed.

Infection with the polioviruses (3 separate enteroviruses) causes a nonspecific illness. These viruses have tropism for neurons, particularly those in the anterior horns of the spinal cord, and acute flaccid paralysis is the most serious complication. Vaccination programs eradicated polio from the Western hemisphere. Enterovirus 71 infections cause outbreaks of hand-foot-and-mouth disease in China each year. Enterovirus 71 is linked to neurologic disease in China, with symptoms ranging from meningoencephalitis to acute flaccid paralysis to fatal brainstem encephalitis. The cause of death in patients who have enterovirus brainstem encephalitis is autonomic nervous system dysfunction and acute respiratory distress syndrome. Pulmonary hemorrhage may be part of the spectrum.

In September 2014 the CDC issued a Health Advisory after 9 children in Colorado presented with acute focal limb weakness. Magnetic resonance imaging of the brain and spine demonstrated gray matter changes to the spinal cord. Many of these patients tested positive for enterovirus D68. National news agencies have reported similar presentations in other parts of the country. A recent article discussed the temporal association of enterovirus D68 infection and acute flaccid paralysis.

### Differential Diagnosis

The differential diagnosis of hemorrhagic conjunctivitis infection should include adenovirus. Gingivostomatitis caused by *Enterovirus* species tends to cause lesions on the tongue and pharynx, whereas herpes simplex virus (HSV) types 1 and 2 lesions usually involve the lips and anterior gingiva. *Echovirus* and *Parechovirus* can cause nonspecific febrile illnesses similar to the symptoms of enterovirus. Meningoencephalitis symptoms in infants and young children can present similarly to HSV infection. Unlike herpesvirus, enterovirus does not typically cause seizures. Because HSV disease has high morbidity and mortality, it is important to consider this virus in the differential diagnosis because HSV requires prompt treatment with acyclovir. In young infants, enterovirus infection may present with fever as the only symptom. In the neonate, occult bacteremia, meningitis, and pyelonephritis may also present with fever as the only symptom.

## Diagnosis

Before PCR techniques were available, the detection of *Enterovirus* species required viral culture. Enteroviruses grow slowly in cell culture, and results often required a 2- to 3-week wait. Viremia occurs in the acute phase of illness, and culture obtained after that time has a reduced sensitivity. PCR provides rapid results. Appropriate specimens for PCR testing include blood, cerebrospinal fluid, nasopharyngeal swabs, and rectal swabs.

A lumbar puncture is necessary to diagnose enteroviral meningoencephalitis. Cerebrospinal fluid testing should include cell count, protein, glucose, and bacterial culture as well as PCR. If a contraindication precludes a lumbar puncture, enteroviral PCR of the serum may help diagnose meningoencephalitis in patients with appropriate clinical symptoms. PCR testing of stool samples will detect enteroviruses. Because infants and young children may shed enterovirus in the stool for weeks, a positive test from a stool sample is not adequate to diagnose an enterovirus as the cause of an infection.

## Treatment

There is no specific treatment for *Enterovirus* species infections. Infection resolves after the body mounts an effective antibody response. Provide supportive care based on symptoms. Infants who are dehydrated might require intravenous fluids. Patients with severe respiratory distress may require intubation and mechanical ventilation. There are no commercially available antiviral agents with activity against enteroviruses. The medical literature is mixed on whether pleconaril, an antiviral agent effective against some picornaviruses, had significant activity against enteroviruses other than coxsackieviruses. Pleconaril is no longer available for clinical or research use. Two promising antiviral agents under study include a capsid binder (vapendavir) and a novel protease inhibitor (SG85). Wang and colleagues reported that intravenous immunoglobulin (IVIG) therapy could improve survival in patients with enterovirus brainstem encephalitis. At this time there are no conclusive studies to support the use of IVIG to treat enterovirus infections; however, IVIG therapy is often used to treat immunodeficient patients with enterovirus infections.

## Vaccination

Although oral and inactivated polio vaccines eradicated disease from all areas with high vaccination rates, there is no current vaccine effective against other enteroviruses. In Asia, multiple outbreaks of enterovirus 71 have caused permanent central nervous system disease or death. Inactivated viral particle vaccine studies are underway. The major challenge to the development of an enterovirus vaccine is that some subtypes, such as enterovirus 71, have multiple serotypes. Viruses of varying serotypes can recombine their RNA to create new proteins, which may confer resistance to a vaccine. In animal models, small segments of RNA may protect against disease.

When children present for care, the diagnosis of enterovirus infection is not confirmed. Treatment is supportive, and antipyretics and intravenous fluids

may be appropriate for some sick children. Criteria for referral to a children's hospital include the following:

- Seizures
- Encephalitis
- Acute flaccid paralysis
- Severe respiratory distress

Although the treatment is supportive, pediatric subspecialists in critical care medicine, neurology, radiology, and infectious diseases may be helpful in caring for these patients.

## Prognosis

Herpangina and mild febrile illnesses resolve with time. A sepsis like presentation with hepatitis and coagulopathy in neonates is an uncommon presentation, but the mortality rate is quite high. Encephalitis typically resolves without sequelae. Acute flaccid paralysis may be permanent.

## Prevention

Basic infection control practices prevent most cases of *Enterovirus* species infection. The CDC recommends hand hygiene with soap and water or a waterless alcohol rub. Health care workers should institute contact precautions (gown and gloves). The respiratory transmission of some enteroviruses means that cough etiquette and avoiding nasal secretions may be beneficial. For enterovirus in general, standard and contact precautions should be applied. For respiratory enterovirus infection (such as D68), droplet precaution should be added to standard and contact precautions regardless of the patient's age. When caring for children with respiratory enterovirus infection, consider adding a surgical mask (droplet precautions) as well.

## EBOLA VIRUS DISEASE

### Background

Ebola virus disease (EVD), previously known as *Ebola hemorrhagic fever*, is a severe and often fatal disease of humans and nonhuman primates. The first known EVD outbreak occurred simultaneously in Nzara, Sudan, and Yambuku, Zaire (now the Democratic Republic of Congo) in 1976. The disease received its name from the Ebola River, which passes near the Yambuku village in the Democratic Republic of Congo.

*Ebolavirus* is a genus in the family Filoviridae. Five species of *Ebolavirus* have been identified: Zaire Ebola virus, Sudan Ebola virus, Taï Forest Ebola virus, Bundibugyo Ebola virus, and Reston Ebola virus. Reston Ebola virus is not known to cause disease in humans. Given its extremely contagious nature both in the community and health care settings, a single case is considered an outbreak. In 2013 to 2014, the largest outbreak in recorded history started in Guinea and spread to Liberia, Sierra Leone, Nigeria, Mali, and Senegal in Africa. The suspected index case of this outbreak is thought to be a 2-year-old child who died in Guinea. This outbreak from Zaire Ebola virus has resulted in more than 27,000 confirmed cases and more than 10,500 deaths, based on the World Health Organization Ebola situation report on July 15, 2015. The total case-fatality proportion from prior outbreaks

in 1976 to 2008 is 79%, with the Zaire Ebola virus species carrying the highest risk for mortality. In the most recent outbreak in West Africa, individuals aged 15 to 44 years were approximately 3 to 4 times more likely to be affected by EVD than children 14 years and younger. The low number of pediatric EVD cases may result from cultural practices in which children are kept away from sick family members, resulting in reduced risk for Ebola virus exposure.

### Pathogenesis and Disease Transmission

Fruit bats are hypothesized to be the natural reservoirs of Ebola virus; however, this has not been confirmed. The hypothesis is that bats pass the virus on to other animals, such as apes, gorillas, and monkeys, and the virus is then transmitted to humans through the preparation of raw meat or butchering. Human-to-human transmission occurs by direct contact with blood, organs, secretions, and other body fluids (eg, urine, feces, semen, sweat, human milk, mucus, and vomit) of an infected person (alive or dead), as well as with surfaces and materials contaminated with these fluids. Infected medical supplies (eg, syringes and needles) and equipment are additional ways in which the virus can be transmitted from human to human. Virus persistence in the environment depends on many factors, including exposure to sunlight, temperature, and the material surface. It is not known to spread through air or water or by mosquito. The incubation period for EVD is 2 to 21 days. Children younger than 1 year exhibit a shorter incubation period than older children 10 to 15 years of age (6.9 days vs 9.8 days).

### Clinical Presentation

EVD symptoms can resemble other common febrile diseases, such as malaria, enteric fever, or dengue fever. In the early phase of the disease (days 1 to 7), symptoms include a sudden onset of high fever, loss of appetite, headache, nausea, emesis, abdominal pain, diarrhea, myalgia, arthralgia, intense fatigue, and conjunctivitis. A challenge facing physicians caring for children is being able to distinguish the signs and symptoms of early EVD from the features of much more common infectious diseases. In the late phase (day 8 and beyond), symptoms may include severe diarrhea and vomiting with significant hypovolemia, maculopapular rash, and hiccups. In severe cases, the patient may develop cerebral edema, respiratory distress syndrome, shock, multiorgan failure, and coagulopathy associated with hemorrhagic complications, such as mucosal hemorrhage, epistaxis, hemoptysis, hematemesis, rectal bleeding, hemorrhagic stroke, and uncontrolled bleeding from venipuncture sites. Routine laboratory evaluations generally yield leukopenia, thrombocytopenia, hyponatremia, hypokalemia, hypocalcemia, hypoalbuminemia, and elevated liver enzymes.

The case-fatality proportions in the recent outbreak are 73% for children younger than 15 years, 66% for those aged 15 to 44 years, and 80% for those older than 44 years. Children younger than 5 years had more rapid disease progression and a higher fatality rate compared with older children. Pregnant women

are more likely to have a spontaneous abortion and hemorrhagic complications. Neonates born to mothers with acute Ebola infection have not survived thus far.

Patients are considered infectious as long as they are symptomatic and as long as their blood and secretions contain the virus. It is currently unknown how long the virus can persist in sequestered areas of the body, such as the testicles, where the virus has been shown to be present in semen for more than 3 months, and the eye, where the virus has been demonstrated in the aqueous humor 14 weeks after the onset of EVD. Disability may persist after recovery because of complications of hemorrhage, such as hemiplegia from stroke. Moreover, survivors have reported extreme fatigue, arthralgia, myalgia, abdominal pain, anorexia, tinnitus, and hearing loss. Arthralgia has been described to be asymmetric and sometimes migratory involving large joints. Arthralgia and myalgia could persist up to 21 months after EVD onset. Late ophthalmologic manifestations have been reported among EVD survivors. These include ocular pain, photophobia, hyperlacrimation, and loss of visual acuity as a result of uveitis.

A high index of suspicion and active case surveillance are the key to diagnosis. Persons with the previously mentioned clinical symptoms who have traveled to or had contact with an ill traveler from an area where Ebola transmission is active should be evaluated and closely monitored for EVD. Laboratory diagnosis for EVD includes the detection of virus in blood specimens using real-time reverse-transcriptase PCR, and viral antigen detection by enzyme-linked immunosorbent assay (ELISA). Specific antibodies to Ebola virus may be detected by immunoglobulin (Ig) G and IgM ELISA or IgM capture ELISA starting a few days after symptom onset. However, patients with fatal disease may not develop detectable antibody responses. In the absence of these diagnostic tests in a resource-limited setting, a case definition based on clinical criteria can be used if the epidemiologic conditions support the diagnosis of EVD (ie, region with prior outbreak or travel from outbreak area).

### Treatment

Standard treatment consists of aggressive oral and intravenous fluid replacement, maintenance of electrolyte balance, and transfusion of blood products as necessary. Such treatments seem to be critical for a positive outcome in patients with EVD. Severely ill patients may require intensive care, which can include the need for dialysis, mechanical ventilation, or both. EVD survivors should be monitored and treated for long-term complications. Psychosocial support is often required to support the reentry of survivors into their communities. Currently, no approved specific therapy is available that has demonstrated efficacy in the treatment of EVD. Experimental treatments, including a plant-based monoclonal antibody therapy called ZMapp and the transfusion of blood products donated by EVD-recovered patients, were used to treat a small number of patients during the most recent outbreak. Several treatments are being evaluated in clinical trials at the time of this

writing; these include ZMapp, favipiravir, and convalescent blood products from patients who recovered from EVD.

### Prevention

No vaccines are approved for humans or animals, although several vaccine candidates are currently being tested. At the time of this writing, 2 Ebola vaccines using a chimpanzee adenovirus vector and vesicular stomatitis virus vector are being evaluated in phase II/III trials in Africa.

In the absence of effective treatment and vaccines, public awareness, proper patient isolation, and contact tracing are the keys to reduce human infection and death. For symptomatic patients with potential Ebola virus exposure, patient isolation and public health authority notification should be immediately implemented to arrange for safe transport to an appropriate health care facility. For asymptomatic persons with potential Ebola virus exposure, public health officials may implement either active monitoring or direct active monitoring, depending on the individual's exposure risk. Active monitoring consists of daily reporting of measured temperatures and symptoms by the individual to the public health authority, whereas direct active monitoring designates that a public health authority directly observes the individual at least once daily to review symptom status and monitor temperature, with a second follow-up per day being conducted by phone. Exclusion of the person from public places and travel restriction could be enforced by public health authorities. In general, all travelers from the outbreak region are monitored for 21 days after their last date of possible exposure to the virus. Infection among health workers may be prevented by strict adherence to infection prevention and control practices (such as proper hand-washing technique, appropriate use of personal protective equipment [PPE], and proper waste disposal of contaminated material). In pediatric settings, the presence of a family member might be needed in caring for children with EVD. A child with mild symptoms (eg, no bleeding, vomiting, or diarrhea) could be isolated with a family member so that the child can continue to be nurtured and supported while ill. This needs to be balanced with appropriate infection control procedures, including the use of PPE. To prevent sexual transmission of infection during the convalescent period, the World Health Organization recommends abstinence from all sexual activities for 6 months after the symptom onset or practicing safe sex through correct and consistent condom use until their semen has twice tested negative by reverse-transcriptase PCR. This interval may be adjusted as new information on sexual transmission of Ebola virus becomes available. The bodies of deceased individuals remain infectious and must receive safe burials as defined by the use of PPE before touching, washing, or manipulating the body and the use of a leak-proof body bag or coffin. Abstention from traditional practices, such as dressing or washing a body before the funeral, is necessary to avoid the infection of health workers who transfer a body and the infection of family,

community members, or funeral workers who participate in funerals.

## Chapter 249 ENURESIS

Franca M. Iorember, MD, MPH

The acquisition of urinary continence is part of the transition from infant to child lower urinary tract function. Although incontinence in a child can be an

inconvenience, it is generally tolerated until a child falls behind her peers. Since parental concerns about voiding are common, it is important for primary care physicians to have an understanding of both the normal acquisition of continence and departures from those normal patterns. This chapter will provide the basis for the primary care physician to understand the definition, epidemiology, etiology, risk factors, differential diagnosis, evaluation, and management of enuresis in children.

## DEFINITION OF TERMS

### Definitions

Enuresis refers to intermittent urinary wetting while asleep and is defined as voiding on beds and clothes that occurs at least twice per week for at least 3 consecutive months in a child who is at least 5 years of age. Five years is considered the age of anticipated bladder control at night. Children who are mentally disabled should, therefore, reach a mental age of 5 years before they are considered enuretic. “Nocturnal” is often added to enuresis for more clarity. The child who wets during the daytime and at night has daytime incontinence and enuresis (or nocturnal enuresis). The term diurnal enuresis has been dropped. Enuresis is described as *primary* when it occurs in children who have never had a period of sustained dryness and *secondary* when it occurs in children who have been dry in the past for a period of at least 6 months. Nocturnal enuresis can be *monosymptomatic* when there are no other lower urinary tract symptoms, such as increased/decreased voiding frequency, daytime incontinence, urgency, hesitancy, straining, a weak stream, intermittency, holding maneuvers, a feeling of incomplete emptying, postmicturition dribble, and genital or lower urinary tract pain. When other lower urinary tract symptoms are present, enuresis becomes *nonmonosymptomatic* (polysymptomatic).

### Epidemiologic Mechanism

The available data on the prevalence of nocturnal enuresis need to be treated with caution given the inconsistency in methodology across epidemiologic surveys. Nocturnal enuresis occurs in approximately 20% of children at 5 years of age. At age 7, the prevalence of nocturnal enuresis is between 6% and 10%. In the United States, a recent National Health and Nutrition Examination Surveys (NHANES) study of children aged between 8 and 11 years found the prevalence of enuresis to be 4.45%. The annual spontaneous resolution rate is approximately 15%, with nocturnal enuresis persisting in 1% to 3% in the late teens. The incidence of primary enuresis is twice that of secondary enuresis. Nocturnal enuresis is 2 to 3 times more common in boys than girls and is monosymptomatic in more than two-thirds of cases. Daytime wetting is more likely in females. Ten percent of 5-year-olds experience daytime wetting at least once every 2 weeks.

### Etiology

A strong hereditary component to nocturnal enuresis has been noted. Twin studies demonstrate a concordance rate of 19% to 36% for dizygotic twins and 46% to 68% for monozygotic twins. Children with a

family history of nocturnal enuresis are more likely to experience nighttime wetting than their peers. Forty-four percent of children with 1 parent with a history of nocturnal enuresis will also have nocturnal enuresis; the percentage of affected children increases to 77% if the history of nocturnal enuresis is present in both parents. The inheritance pattern with nocturnal enuresis is most often autosomal dominant with high penetrance. In addition to genetics, developmental factors, such as delayed speech, delayed walking, and early toilet training, have been speculated to be associated with nocturnal enuresis; however, studies evaluating these associations have yielded conflicting results.

Several factors are involved with the pathophysiology of monosymptomatic nocturnal enuresis (MNE). Most children with MNE have relative nocturnal polyuria that exceeds the child's bladder capacity, leading to nighttime wetting. Normally, the secretion of antidiuretic hormone increases during sleep; however, in some children with MNE the secretion of antidiuretic hormone is decreased at night, resulting in increased urine production. Voided volumes have been demonstrated to vary in the daytime and nighttime. In children with enuresis, voided volumes have been found to be smaller at night compared to normal controls, suggesting some form of overactive bladder. Normally, if a child had a full bladder, whether caused by nocturnal polyuria or overactive bladder, he would awaken and void in an appropriate place. However children with MNE are more difficult to arouse from sleep than normal controls, or children with polysymptomatic nocturnal enuresis. Enuresis has been reported to be associated with some sleep disorders, particularly obstructive sleep apnea. Nocturnal enuresis is present in 33% of children with obstructive sleep apnea and resolves in 61% and decreases in 23% of children within 9 months following tonsillectomy and adenoidectomy. The presence of nocturnal hypercalciuria and aquaporin-2 dysfunction have also been postulated to play a role in the pathogenesis of enuresis.

Anatomic abnormalities may also contribute to nonmonosymptomatic enuresis. Urethral obstruction, as a result of posterior urethral valves or urethral stricture, is known to cause daytime incontinence or nocturnal enuresis. Ectopic ureters in females may lead to continuous leaking of urine because, unlike in males, the ectopic ureter does not insert proximal to the external sphincter. Lesions involving the spinal cord often result in a neurogenic bladder, which can lead to enuresis. However, the prevalence of spina bifida occulta has not been shown to be statistically different between children with functional bowel or urinary problems and age- and gender-matched controls. Vesicovaginal reflux occurring in females may lead to urine leakage and contribute to incontinence in these patients.

Daytime incontinence occurs when urine is held until the last minute, a behavior common in preschoolers and older children who avoid the restroom at school. Other forms of daytime urinary incontinence include increased daytime voiding frequency resulting

from an overactive bladder, wetting during coughing or sneezing as is seen in stress incontinence, and wetting during laughter in giggle incontinence. Attention-deficit/hyperactivity disorder (ADHD) has also been shown to be strongly associated with enuresis. Urinary tract infection (UTI) contributes to enuresis when cystitis causes spontaneous detrusor contractions; also, UTIs are more common in children who have abnormal genitourinary anatomy. Other risk factors that have been demonstrated to be associated with nocturnal enuresis include encopresis and emotional stress.

## DIFFERENTIAL DIAGNOSIS

Although enuresis is most often encountered as a primary disorder, it also may present secondary to other conditions. Underlying disorders that should be considered in the evaluation of enuresis are listed in Box 249-1.

## EVALUATION

### History

The history is a critical component in the evaluation of enuresis. A thorough history will help the pediatrician categorize the type of enuresis present and identify underlying conditions that might be contributing to the patient's symptoms. The International Children's Continence Society recommends the use of structured questionnaires for parents to complete prior to the evaluation. The questionnaire is available on request from the authors directly.

The time of onset, frequency, time of day of occurrence, and any relationship with environmental changes should be determined. It is important to obtain a history on the length of time of dryness prior to the onset of enuresis. The history of dryness is important because it makes the presence of a structural urinary problem unlikely, helps predict the chance of eventual dryness, and decreases the need for extensive

investigation. It is helpful to know the child's fluid intake and drinking habits, because some children drink large volumes of fluid in the evening, which may precipitate or exacerbate enuresis. Symptoms of polydipsia, polyuria, and recent weight loss may suggest diabetes mellitus. A history of symptoms such as urinary frequency, urgency, and dysuria should be obtained to help determine the presence of a UTI. It is important to determine the child's feelings about the symptom and any motivation for doing something about it, as this would eventually influence the decision to initiate therapy. It is also important to elicit what the child and parents have done about the symptom prior to this evaluation. A history of the child's sleeping patterns needs to be obtained because of the association of enuresis and sleep apnea. Symptoms of snoring and mouth breathing while asleep, restless sleep, and tiredness on waking up in the morning should be elicited in the history. In females, a history of being always wet might suggest ectopic ureter. A summary of questions to consider while taking a history of a child with enuresis are listed in Box 249-2.

Past medical history, including a thorough perinatal history, should be sought to determine if there are any neurologic explanations for enuresis. Specifically, a history of spina bifida or meningocele would be important in the pathogenesis of enuresis. Any history of delayed developmental motor milestones or spinal trauma should be obtained. Constipation in the child must be ruled out because of the strong association of constipation with enuresis. Any family history of enuresis or idiopathic hypercalciuria should be elicited because this would help in evaluating the cause of enuresis. Psychologic problems and psychosocial stressors are known to be associated with enuresis. These include poor self-esteem, chronic anxiety, child abuse, and delayed development.

### Physical Examination

Physical examination findings of the child with enuresis are often normal, but the examination should be thorough and focus on signs that may indicate any of the causes of enuresis. Abnormal vital signs or growth parameters may be an indication of chronic disease. A thorough oropharyngeal examination may reveal the presence of tonsillar enlargement, especially in a child with suspected obstructive sleep apnea. A complete neurologic examination, including an assessment of gait, muscle tone and strength, deep tendon reflexes, sensory abnormalities, and rectal sphincter tone, is necessary to exclude central nervous system disease, which may result in enuresis. An examination of the spine may reveal subtle signs of spinal dysraphism, such as dimples, hair tuft, and skin discoloration. Let the child grasp a pencil with his toes: if he is able to do so, it means that S1, S2 and S3, are intact. Ask him to do it bilaterally. An abdominal examination should pay particular attention to the presence of a distended bladder or constipation. A distended bladder may suggest the presence of an obstructing urethral lesion such as posterior urethral valves or stricture. The presence of constipation increases the risk of urinary

### BOX 249-1 Medical Conditions Associated With Enuresis

1. Urinary tract infections
2. Neurologic disorders, including neurogenic bladder or detrusor instability, and spinal cord pathology
3. Structural genitourinary tract abnormalities, including ectopic ureter, posterior urethral valves, urethral stricture, and vesicovaginal reflux
4. Constipation
5. Endocrine disorders, including diabetes mellitus and diabetes insipidus
6. Hypercalciuria
7. Sickle cell disease
8. Drugs, including caffeine and methylxanthines
9. Obstructive sleep apnea
10. Psychosocial stressors, including child abuse, parental divorce or separation, and death in the family

**BOX 249-2 Questions to Consider When Taking a History of a Patient With Enuresis**

1. Definition of the enuresis:
  - Determine between nocturnal and diurnal enuresis
    - *Does the wetting occur during the day, the night, or both?*
    - *How often does the wetting occur and at what times?*
    - *How often does the child void during the day and during the night?*
2. Type of enuresis:
  - Determine between primary and secondary enuresis
    - *At what age did the wetting start?*
    - *Has the child ever been dry? If so, for how long?*
    - *Has the child had any dry spells?*
    - *How long did dry spells last?*
3. Identify what the social situation is regarding the enuresis
  - How does the family handle wet nights?
  - Does the child wear training pants or is a plastic sheet used?
  - If sheets and clothing require laundering, who is responsible?
  - Do siblings tease the child?
  - Is the child punished for wetting?
  - Have there been any recent traumatic events or changes in the child's social situation at home or in school?
4. Identify fluid intake during the day and prior to bedtime
  - How much and how often does the child drink in the daytime?
  - How much and when does the child drink after supper?
5. Define sleep habits
  - Is the child difficult to awaken from sleep?
  - Are signs of obstructive sleep apnea (mouth breathing, snoring, and restless sleep) present?
6. Evaluate for daytime symptoms
  - Is urinary frequency (the normal frequency of voiding is 4–7 times/day), urgency, or dysuria present?
  - Is dribbling present between voids?
  - Does the child strain with voids?
  - Is the child always wet?
  - Is constipation present?
7. Evaluate past medical history and family medical history
  - Has the child had normal development?
  - Does the child have any psychologic conditions (ADHD, depression, or behavior disorders)?
  - Is there a family history of enuresis?
  - Has the child had any surgery?
  - Is there any history of polydipsia and polyuria?
  - Is there any history of recent weight loss?

tract infections. Flank examination should exclude the presence of renal masses that may indicate renal diseases. Lower abdominal tenderness may indicate a UTI. A careful genitourinary examination should be performed to evaluate for the presence of a rash, adhesions, trauma, foreign body, and, in girls, vulvitis and vaginitis. A rectal examination can reveal the presence of fecal impaction or decreased rectal tone. In some instances, observing a child void may reveal important clues to the presence of urethral obstruction, such as a weak urine stream and straining during micturition.

### Laboratory Investigations

The diagnosis of enuresis is largely dependent on a thorough history and physical examination. With MNE, a simple urinalysis can provide valuable information about the cause of enuresis. The presence of proteinuria, hematuria, and red blood cell casts may signal renal pathology, while glucosuria may be an indication of diabetes mellitus. A low specific gravity on urinalysis may be associated with diabetes insipidus or psychogenic polydipsia. The presence of white blood cells and bacteria may suggest a UTI, which may then be confirmed on a urine culture. If daytime symptoms are present or if the initial laboratory evaluation and physical examination reveal abnormalities, additional evaluations are indicated. Imaging studies should start with pre- and post-void renal and bladder ultrasound.

If the renal ultrasound is abnormal, a voiding cystourethrogram and urodynamic studies should be considered. If a spinal dysraphism is suspected, magnetic resonance imaging of the spine should be ordered.

### MANAGEMENT

Treatment of MNE should be considered in a child who is 6 years of age or older and must begin with careful and detailed explanation of the condition to both parents and child in language that is easily understood. The treatment of MNE is often a frustrating experience for both parents and child, as relapses often occur. The combination of a motivated child and a cooperative family is the best predictor of a positive outcome. Treatment programs should be individualized and realistic goals set for both the patient and the family. Primary and secondary nocturnal enuresis are treated similarly.

The options available for the treatment of enuresis depend on the presence or absence of any organic causes as previously discussed. Any underlying pathology must be addressed. Common organic causes of enuresis such as constipation or UTI, if present, should be treated first. Constipation has been shown to be a commonly unrecognized and undertreated cause of enuresis. If both daytime and nighttime symptoms are present, the daytime symptoms should be the initial focus. Good voiding hygiene and habits should be reinforced.

### Nonpharmacologic Therapy

Conservative measures that help minimize nocturnal polyuria include decreasing the amount of fluid intake several hours before bedtime. Voiding prior to going to bed minimizes the nocturnal bladder volume. The child may also be awakened and taken to the bathroom to urinate before parents go to bed. Other measures that have been shown to reduce the number of wet nights include the use of charts, mainly for positive reinforcement. Children are asked to fill out a chart depicting wet and dry nights symbolically (such as “stars” or “sun” for dry nights and “cloud” for wet nights). During the daytime, the child should be encouraged to void often and take the time to empty the bladder completely. In most cases of daytime incontinence, this helps alleviate symptoms. It is prudent to ask the child to void in the morning, at least twice during the school day, after school, at dinner time, and just before turning out the lights and going to sleep.

### Specific Therapy

The first-line therapy for MNE is either the enuresis alarm or desmopressin (DDAVP). For the well-motivated child and well-informed family, the enuresis alarm might be the initial choice. Families who are not as well motivated, who have had no success with the alarm (accurately used), or who are considered unlikely to fully comply with alarm treatment might do better with DDAVP.

#### Alarm

The bedwetting alarm has been shown to be very effective in the treatment of MNE. It is worn by the child every night. The alarm is triggered when a sensor in the sheets or night clothes becomes wet, setting off an auditory signal that then awakens the child. It must be emphasized to the family that response to the alarm is not immediate and patience is needed for successful therapy. The alarm should be used for 2 to 3 months or until the child is dry for 14 consecutive nights, whichever comes first. Although the response rate is not as rapid, alarm therapy is more effective than pharmacologic therapy in the treatment of enuresis. The response rate to the alarm is high in families who continue treatment for a sufficient period, with relatively low relapse rates. Relapses do not preclude future success. The percentage of children who remain dry long-term after alarm therapy is stopped is 47%, suggesting that the alarm is not only a management modality but also a cure. In some families, alarms may increase parental annoyance and place the child at risk for physical or emotional abuse. Physicians managing these children should follow up closely with families to identify areas of difficulty early and address concerns. Many children will not initially awaken with the alarm and need a parent to assist in awakening, so it is helpful for a parent to sleep in the room with the child. If the child seems not be able to wake up from the alarm after a short time (eg, 1–2 weeks), the treatment should be discontinued and eventually repeated at a later stage.

### Pharmacologic Therapy

The pharmacologic management of enuresis is dependent on the cause of the condition. Historically, 3 drugs have been used in the treatment of enuresis: DDAVP, imipramine, and oxybutynin.

#### Desmopressin

DDAVP is an analogue of vasopressin (also called antidiuretic hormone). Vasopressin is a polypeptide of 9 amino acids and is produced in the hypothalamus and released from the pituitary gland. The stimulus for the release of vasopressin is hyperosmolarity or intravascular volume depletion. Vasopressin acts on the collecting ducts and distal tubules in the kidney to enhance water reabsorption and also has vasopressor effects. DDAVP, on the other hand, has significantly increased antidiuretic activity, but absent vasopressor effects. DDAVP is used for the treatment of MNE. It has a dose-dependent effect, and the usual dose is 0.2 mg up to 0.6 mg orally at bedtime. Response to treatment might take up to 2 to 3 months. If treatment with DDAVP is successful, a 1-week interruption every 3 months is recommended to see if enuresis has resolved. In children in whom there is no response to DDAVP, alarm therapy should be considered if the child and the family are motivated. In the short term, DDAVP is reported to produce a more rapid improvement than alarm therapy, but in the long term, the alarms are more effective and have the highest overall cure rate in treating enuresis. Relapse is common with DDAVP use, with many children wetting again when treatment is stopped. Patients and parents should be educated on the side effects of DDAVP, some of which include nausea, vomiting, abdominal pain, headache, facial flushing, elevated blood pressure, chest pain, tachycardia, and hyponatremia from water intoxication. It is therefore important to screen the child with a good voiding diary and to exclude evening or nighttime polydipsia. Hyponatremia is particularly concerning. Recent data have suggested that there is decreased risk of hyponatremia with oral DDAVP compared to the intranasal formulation. Consequently, the US Food and Drug Administration has advised physicians not to use DDAVP in its intranasal form for the treatment of MNE. In children who do not respond to monotherapy with DDAVP or alarm therapy, combination therapies using both DDAVP and alarm may be considered as second-line therapy and have been shown to be effective in achieving dryness.

#### Oxybutynin

Oxybutynin is an anticholinergic as well as a smooth-muscle relaxant and has been useful in the treatment of daytime enuresis caused by detrusor overactivity. This drug may therefore be of benefit to those children with enuresis who have restricted bladder capacity because of bladder overactivity. The dose is 5 mg of oxybutynin at bedtime, but this dose may need to be doubled. Side effects of oxybutynin include nausea, vomiting, abdominal pain, diarrhea or constipation, urinary retention, dry mucous membranes, and blurred vision. Given alone, oxybutynin has been

shown to be no more effective than placebo in the treatment of primary enuresis. However, oxybutynin and the extended-release anticholinergic tolterodine may be helpful if given in combination with DDAVP in those who do not respond to DDAVP monotherapy. This combination has been shown to produce rapid results in the treatment of MNE. In addition to enuresis, anticholinergic medications are used to treat urge syndrome, Hinman syndrome, and the neurogenic bladder.

### Tricyclic Antidepressants

Tricyclic antidepressants, such as imipramine, are a last-line treatment option for MNE in patients who do not show any response to other treatment strategies. It is unclear how these medications produce their effects. It was previously thought that their effects were through their anticholinergic properties, but recent data have shown that patients who do not respond to anticholinergics can benefit from the use of imipramine. The efficacy of imipramine in the treatment of MNE is low, and relapse rates are high. Because of the potential for lethal effects in the setting of an accidental or intentional overdose, physicians should be cautious with the use of tricyclic antidepressants such as imipramine. In addition, imipramine may cause nausea, vomiting, constipation, blurry vision, urinary retention, cardiac arrhythmias, and hypotension. The anti-enuretic dose is 25 to 50 mg at bedtime, with the larger dose given in children older than 9 years of age. If tricyclic antidepressants are used, families must be aware not only of the dangerous potential of overdose, but also of safe storage practices and the need for supervision during administration.

### Other Therapies

Behavioral modifications, such as changes in toileting habits, waking after several hours of sleep to void, and the use of alarms, have formed an important aspect of management in patients with enuresis. A recent prospective, randomized study comparing the use of DDAVP and intensive behavior modification showed significant reductions in primary MNE in both arms of the study, with no significant difference between the 2 groups.

## SUMMARY

Several factors may contribute to nocturnal enuresis, including a genetic predisposition, decreased voided volumes caused by an overactive bladder, increased nocturnal urine production, and a diminished capacity for arousal from sleep. Because nocturnal enuresis may present secondary to organic causes or in association with other symptoms, a detailed history and physical examination are critical components of the evaluation. Once organic causes have been ruled out and daytime symptoms have been treated, intervention may be of benefit. Alarm treatment has the best long-term results, but does not provide immediate resolution of symptoms. Treatment, which often includes a combination of behavior and pharmacotherapy, may be individualized based on the needs of a

wide variety of patients. Because involvement of families is an important component in the management of enuresis, parents can be directed to relevant resources such as the publication *Waking Up Dry: A Guide to Help Children Overcome Bedwetting* by Howard J. Bennett, MD, or the National Kidney Foundation Parent Resource Web site at [www.kidney.org/patients/bw/BWparents.cfm](http://www.kidney.org/patients/bw/BWparents.cfm).

## WHEN TO REFER

- Abnormal urinalysis findings suggestive of a metabolic disorder
- Concerns about a neurologic bladder dysfunction
- Failure to respond to appropriate therapy
- Presence of any structural urinary tract abnormalities on imaging studies
- History of recurrent urinary tract infections
- History of significant constipation and encopresis
- History and findings suggestive of obstructive sleep apnea
- Significant behavioral or emotional problems
- Significant parent-child conflict or parental difficulties with coping with child's enuresis
- Attention deficit or learning problems

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 250

## FETAL ALCOHOL SPECTRUM DISORDERS

Leigh Anne Flore, MD, MS

## DEFINITION

Fetal alcohol spectrum disorders (FASD) refer to a continuum of physical, growth, and neurobehavioral abnormalities that occur as a result of prenatal exposure to alcohol. Since 1968, when researchers published a report highlighting the adverse effects of alcohol in offspring of mothers with heavy prenatal alcohol use, thousands of human and animal studies or reports have emerged that demonstrate the range of damaging effects of fetal alcohol exposure. Despite increasing awareness of the adverse effects of maternal alcohol consumption, prenatal alcohol exposure remains among the leading causes of developmental disability worldwide, and is considered to be the most common preventable cause of intellectual disability in the United States.

Several disorders fall under the umbrella term of FASD (Box 250-1), which by itself is not a specific diagnosis but refers to a group of disorders with overlapping physical, behavioral, and cognitive features. Fetal alcohol syndrome (FAS) describes individuals

who fit a well-defined set of clinical diagnostic criteria, including characteristic dysmorphic facial features, evidence of growth restriction, and neurocognitive deficits, in the presence of definite or unknown prenatal alcohol exposure. Fetal alcohol syndrome represents the most severe end of the FASD spectrum; however, the milder forms of FASD are much more common and at the same time often very challenging to diagnose accurately, since distinctive facial features or growth patterns may not be present. Further complicating the diagnosis of FASD, particularly in individuals who do not meet the criteria for full FAS, is the fact that while there are several published guidelines for the diagnosis of FASD, they are not all consistent with each other. However, correct diagnosis is important because individuals with the so-called milder types of FASD may nonetheless have significant, life-long deficits in behavior or cognition, as prenatal alcohol exposure is particularly harmful to the developing brain. Other disorders in the FASD spectrum include partial fetal alcohol syndrome, alcohol-related birth defects (ARBD), and alcohol-related neurodevelopmental disorder (ARND), as defined by the revised Institute of Medicine FASD diagnostic criteria. Partial fetal alcohol syndrome can be diagnosed with or without confirmed maternal alcohol exposure, and encompasses children with characteristic facial features of FAS and *either* growth deficiency or central nervous system (CNS) abnormalities. The term ARBD is used

## BOX 250-1 Fetal Alcohol Syndrome and Related Disorders

1. Fetal alcohol syndrome (FAS)
  - a. Requires all 3 of the following findings:
    - i. Documentation of all 3 facial abnormalities (smooth philtrum, thin vermillion border, and small palpebral fissures)
    - ii. Documentation of growth deficits
    - iii. Documentation of CNS abnormality
  - b. Facial dysmorphism (all 3 must be present)
    - i. Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
    - ii. Thin vermillion border of the upper lip (University of Washington Lip-Philtrum Guide rank 4 or 5)
    - iii. Small palpebral fissures (length at or below 10th percentile)
  - c. Growth deficiency: Prenatal or postnatal height or weight (or both)  $\leq$  10th percentile, documented at any point in time and adjusted for age, sex, gestational age, and race/ethnicity
  - d. CNS abnormalities: 1 of the following, or a combination thereof
    - i. Structural abnormalities
      - (a). circumference at or below the 10th percentile adjusted for age and sex
      - (b). significant brain abnormalities observable through imaging
    - ii. Neurologic abnormalities: Neurologic problems not caused by a postnatal insult or fever or other soft neurologic signs
    - iii. Functional abnormalities: Performance substantially below that expected for an individual's age, schooling, or circumstances, as evidenced by either:
      - (a). Global cognitive or intellectual deficits representing multiple domains of deficit (or significant developmental delay in younger children) with performance below the 3rd percentile ( $-2$  SD for standardized testing)
      - (b). Functional deficits below the 16th percentile ( $-1$  SD for standardized testing) in at least 3 of the following domains:
        - Cognitive or developmental deficits or discrepancies
        - Executive functioning deficits
        - Motor functioning delays
        - Problems with attention or hyperactivity
        - Social skills
        - Other, such as sensory problems, pragmatic language problems, memory deficits, etc
  - e. Maternal alcohol exposure may be confirmed or unknown.

Continued

**BOX 250-1 Fetal Alcohol Syndrome and Related Disorders—cont'd**

2. Partial FAS (PFAS) with confirmed maternal alcohol exposure: requires all 3 of the following findings:
  - a. Confirmed maternal alcohol exposure
  - b. At least 2 of the following facial characteristics:
    - i. Small palpebral fissures (length at or below the 10th percentile)
    - ii. Thin vermilion border of the upper lip (University of Washington Lip-Philtrum Guide rank 4 or 5)
    - iii. Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
  - c. One of the following other characteristics:
    - i. Height or weight at or less than the 10th percentile for age, sex, ethnicity
    - ii. Evidence of structural CNS abnormalities, including at least 1 of the following:
      - (a). Head circumference at or less than the 10th percentile
      - (b). Structural brain abnormalities
    - iii. Evidence of a complex pattern of behavioral or cognitive abnormalities inconsistent with developmental level that cannot be explained by genetic predisposition, family background, or environment alone, including:
      - (a). Marked impairment in performance of complex tasks
      - (b). Higher-level receptive and expressive language deficits
      - (c). Disordered behavior
3. Alcohol-Related Birth Defects (ARBD) - Requires all 3 of the following findings (a, b, c)
  - a. Confirmed maternal alcohol exposure
  - b. At least 2 of the following:
    - i. Small palpebral fissures (length at or below the 10th percentile)
    - ii. Thin vermilion border of the upper lip (University of Washington Lip-Philtrum Guide rank 4 or 5)
    - iii. Smooth philtrum (University of Washington Lip-Philtrum Guide rank 4 or 5)
  - c. Congenital structural defects in 1 or more of the following categories, including malformations and dysplasias (if the patient displays minor anomalies only, 2 or more must be present):
    - i. Cardiac: atrial septal defects, aberrant great vessels, ventricular septal defects, conotruncal heart defects
    - ii. Skeletal: radioulnar synostosis, vertebral segmentation defects, large joint contractures, scoliosis
    - iii. Renal: aplastic/hypoplastic/dysplastic kidneys, horseshoe kidneys, ureteral duplications
    - iv. Ocular: strabismus, ptosis, retinal vascular anomalies, optic nerve hypoplasia
    - v. Ears: conductive hearing loss, sensorineural hearing loss
    - vi. Minor anomalies: hypoplastic nails, short fifth digits, fifth finger clinodactyly, pectus carinatum or excavatum, camptodactyly, "hockey stick" palmar creases, refractive errors, "railroad track" ears
4. Alcohol-related neurodevelopmental disorder (ARND): Requires both a and b
  - a. Confirmed maternal alcohol exposure
  - b. At least 1 of the following:
    - i. Evidence of deficient brain growth or abnormal morphogenesis, including 1 or more of the following:
      - (a). Structural brain abnormalities
      - (b). Head circumference at or below the 10th percentile for age and sex
    - ii. Evidence of a complex pattern of behavioral or cognitive abnormalities inconsistent with developmental level that cannot be explained by genetic predisposition, family background, or environment alone, including:
      - (a). Marked impairment in performance of complex tasks
      - (b). Higher-level receptive and expressive language deficits
      - (c). Disordered behavior

CNS, central nervous system; SD, standard deviation.

From Bertrand J, Floyd RL, Weber MK, et al. Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis. Atlanta, GA: Centers for Disease Control and Prevention, 2004; Hoyme HE, May PA, Kalberg WO, et al. A practical approach to diagnosis of fetal alcohol spectrum disorders: clarification of the 1996 Institute of Medicine criteria. *Pediatrics*. 2005;115(1):39–47; and Senturias Y, Asamoah A. Fetal alcohol spectrum disorders: guidance for recognition, diagnosis, differential diagnosis, and referral. *Curr Probl Pediatr Adolesc Health Care*. 2014;44(4):88–95.

for children with confirmed alcohol exposure, characteristic facial features, and 1 or more specific, congenital structural anomaly, in the absence of growth restriction or neurocognitive deficits. Alcohol-related neurodevelopmental disorder is diagnosed in individuals without evidence of impaired growth or characteristic facial anomalies who have confirmed maternal alcohol exposure and either structural or functional CNS deficits typical of FASD. Alcohol-related neurodevelopmental disorder is estimated to be the most common of all the disorders resulting from prenatal alcohol exposure.

The term *neurodevelopmental disorder associated with prenatal alcohol exposure* (ND-PAE) has been introduced in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* and is roughly equivalent to ARND. The diagnostic criteria for ND-PAE include evidence of "more than minimal" alcohol exposure during pregnancy and impairments in cognition, self-regulation, and adaptive functioning.

In the past, the term *fetal alcohol effects* initially coined as a population-based term rather than a specific clinical diagnosis, was used liberally to refer to children who had anomalies or cognitive deficits

thought to be related to prenatal alcohol exposure, but who did not meet the diagnostic criteria for FAS. However, this term has largely fallen out of favor, as it has no established diagnostic criteria and is therefore considered vague and without clinical utility. Fetal alcohol effects should no longer be used as a diagnostic term.

## EPIDEMIOLOGY

Fetal alcohol spectrum disorders occur worldwide, though specific subpopulations are known to have particularly high prevalence rates. Yearly, about 40,000 infants in the United States are born with adverse effects from prenatal alcohol exposure. According to the Centers for Disease Control and Prevention (CDC), FAS occurs at a rate of approximately 0.2 to 1.5 per 1,000 births in the United States; the Institute of Medicine (IOM) estimates the rate to be 0.5 to 3.0 per 1,000 children in North American communities. The prevalence of FASD is generally estimated to be around 1% in the US general population. Certain populations are known to have significantly higher rates of FASD, including children in the foster care system (rates of FAS may approach 15 per 1,000), youth in the justice system (estimated that >20% have FASD), and the Native American population. Worldwide, higher prevalence of FASD has been reported in certain regions or countries with heavy per capita consumption of alcohol. A well-studied example of this is Russia, particularly in orphanages, where the prevalence of FAS alone is estimated to be about 15 per 1,000 children.

There are many challenges to accurately estimating the incidence and prevalence of FASD, including the difficulty for many physicians to recognize children with subtle physical or cognitive characteristics of FASD, unavailability of prenatal alcohol exposure history (either because of foster care placement, adoption, or social stigma, which may prevent accurate maternal reporting of alcohol use), and frequent reliance on record review methods. For these reasons, many researchers feel that currently available prevalence data may underestimate the true rate of occurrence of FASD in the general population.

## ETIOLOGY, PATHOPHYSIOLOGY, AND RISK FACTORS

Fetal alcohol spectrum disorders occur only in individuals who were prenatally exposed to alcohol. However, the clinical diagnosis of FAS does not always require definitive proof of maternal alcohol use, since the full FAS facial phenotype is so specific that its presence confirms prenatal alcohol exposure when such history is not available. Alcohol from the maternal bloodstream freely crosses the placenta, and the fetus is exposed to the same blood alcohol level present in the mother's blood. The fetus is, however, exposed to the toxic effects of alcohol for longer periods than the mother because of the immaturity of the fetal liver; in addition, the amniotic fluid can act as a reservoir for alcohol. While the total amount of alcohol consumed during a pregnancy is the most important factor determining a fetus's risk for FASD, other important factors include the timing and pattern of

consumption, as well as maternal and fetal genetic factors (including maternal alcohol metabolism). Studies in various animal models, in cell and embryo cultures, and in humans, have demonstrated that ethanol and its metabolite acetaldehyde exert teratogenic effects in a number of ways. These include directly inducing cell damage via apoptosis and release of free radicals. This direct cytotoxicity results in the structural birth defects and dysmorphic features associated with FASD. In addition, ethanol interferes with cell signaling pathways, disrupts cellular differentiation and growth, interferes with DNA and protein synthesis, and inhibits cell migration. The transplacental transfer of nutrients (such as amino acids, folic acid, zinc, and others) is also reduced, indirectly affecting fetal growth because of intrauterine nutrient deprivation.

In 2005, the US Surgeon General issued a statement warning that there is no known safe amount of alcohol that can be consumed during pregnancy. Studies have shown that pregnancies exposed to as little as 1 drink per day have increased rates of miscarriage, preterm delivery, stillbirth, and intrauterine growth restriction. However, the highest risks for FASD seem to be associated with binge drinking (4 or more drinks consumed on 1 occasion). The timing of exposure is also important. There seems to be no period during pregnancy during which use of alcohol can be considered safe for the developing embryo/fetus. Exposure during the third to eighth weeks of gestation is associated with the highest risks for organ-specific birth defects as well as facial dysmorphism. While structural defects of the CNS, particularly the corpus callosum, can occur as a result of alcohol exposure prior to 8 weeks, the brain continues to develop throughout pregnancy, and the CNS remains vulnerable to the effects of alcohol through the end of the third trimester. First-trimester alcohol exposure is associated with the highest risks for microcephaly, but growth restriction can be seen in fetuses exposed at any time during pregnancy, including the third trimester. Exposure in the second trimester is particularly associated with increased rates of fetal loss.

Both animal and human studies have shown that pharmacogenetic factors may influence a fetus's susceptibility to alcohol-related effects. Genetic differences in either the mother or the fetus may affect the metabolism of alcohol, and lead to increased or decreased sensitivity to prenatal alcohol exposure. Other maternal risk factors that have been associated with higher rates of FASD include history of a previous child with FASD, higher maternal age, increasing number of pregnancies, poor maternal nutrition, and lower socioeconomic status.

## DIAGNOSIS

### Signs and Symptoms

The diagnosis of FAS and other FASD lies primarily in the history and physical examination, with other specific evaluations or tests, such as a neuropsychological evaluation and sometimes neuroimaging or other neurologic testing (eg, electroencephalography) playing a supportive role. It is important to note that there is no single consensus guideline for the diagnosis of FASD;

multiple published guidelines exist, not all of which are completely consistent with each other. Specific diagnostic criteria have been established by the National Center on Birth Defects and Developmental Disabilities at the CDC in collaboration with the National Task Forces on Fetal Alcohol Syndrome and Fetal Alcohol Effect. Similar diagnostic criteria were published by Astley in 1997, revised in 2004, and validated in 2013 (using data from the Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network) and by the IOM (published in 1996, with proposed revisions by Hoyme and colleagues in 2005).

Although a wide range of minor facial and other physical anomalies have been associated with FAS, clinical research has determined that 3 midline characteristics are discriminant for FAS: short palpebral fissure length, smooth philtrum, and a thin upper lip (Figure 250-1). Palpebral fissure length, which is measured from the inner corner to the outer corner of the eye while the child's eyes are open, is plotted on a nomogram to determine the standard deviation from the mean based upon the child's age. The University of

Washington Lip-Philtrum guides (Figure 250-2) allow scoring of philtrum smoothness and upper lip thinness on a 5-point Likert scale; one guide is utilized for whites and a second guide is used for blacks and all other ethnicities with lips similar to blacks. A diagnosis of FAS requires a score of 4 or 5 for both the philtrum and upper lip, as well as palpebral fissure measurement that is less than the 10th percentile for age. Other physical features or anomalies commonly seen in FASD, but not at a frequency or specificity high enough to warrant inclusion as diagnostic criteria, include epicanthal folds, ptosis, an upturned nose, flat nasal bridge, midface hypoplasia, underdeveloped ears (with a "railroad track" appearance, where there is a prominent superior crus of the helix and parallel inferior crus of the antihelix), nail hypoplasia, small and large joint contractures, clinodactyly of the fifth fingers, "hockey stick" palmar creases (upper transverse crease widens and ends between the second and third digits), hirsutism, and congenital cardiac defects.

Growth is measured using standard height/weight measurements and growth curves. Growth deficiency

**Figure 250-1** Examples of the FAS facial phenotype (small eyes, smooth philtrum, and thin upper lip) across 4 races: (A) white, (B) Native American, (C) black, (D) Hispanic. (Copyright 2016, Susan Astley PhD, University of Washington.)

Lip-Philtrum Guide 1

Lip-Philtrum Guide 2

**Figure 250-2** University of Washington Lip-Philtrum Guides 1 (A) and 2 (B) are used to rank upper lip thinness and philtrum smoothness. The philtrum is the vertical groove between the nose and upper lip. The guides reflect the full range of lip thickness and philtrum depth with Rank 3 representing the population mean. Ranks 4 and 5 reflect the thin lip and smooth philtrum that characterize the FAS facial phenotype. Guide 1 is used for whites and all other races with lips like whites. Guide 2 is used for blacks and all other races with lips as full as blacks. (Copyright 2016, Susan Astley PhD, University of Washington.) FAS, fetal alcohol syndrome.

is defined as height or weight that is at or less than the 10th percentile for age/gender as documented at any time (from birth onwards), as long as the poor growth is not thought to be secondary to postnatal influences such as chronic illness or malnutrition.

Structural, neurologic, or functional abnormalities in the CNS may fulfill the third criteria for FAS. Structural anomalies can include microcephaly (defined as head circumference  $\leq$  10th percentile for age/gender) or clinically-significant brain abnormalities of presumed prenatal onset identified on imaging studies. Structural CNS anomalies often observed in children with FASD include abnormalities of the corpus callosum (such as agenesis, partial agenesis, hypoplasia/thinning), cerebellum (particularly of the cerebellar vermis), and basal ganglia, and overall reduction in brain volume. Neurologic criteria can be fulfilled by the presence of seizures (as long as they are not attributable to postnatal events) or abnormal findings on neurologic examination. Functional deficit criteria are met when the child has a global cognitive deficit (eg, low IQ or global developmental delay) or possesses difficulties (scores  $>1$  standard deviation below the mean on standardized testing) in 3 or more of the following areas: cognition/development (such as specific learning disabilities, poor processing, discrepancy between verbal and nonverbal skills), executive functioning, motor functioning, inattention or hyperactivity, social skills, and “other” (which can include sensory problems, memory deficits, and others). Determination of functional CNS abnormalities typically requires formal neuropsychological or other developmental testing. The CNS features of FASD often persist into adulthood. Depending upon the specific neurobehavioral profile of the individual with FASD, there can be considerable risks for secondary disabilities, such as mental health disorders, disrupted school experiences (suspensions, expulsions, drop outs), substance abuse, and involvement with the legal justice system (arrests, incarceration).

Confirmed maternal use of alcohol during pregnancy is not required for a diagnosis of FAS in the presence of all 3 of the above criteria (facial features, growth, and CNS abnormalities). In cases of children who are adopted or are in foster care placement, information about the prenatal history may not be available. In the absence of self-reported maternal history, documentation of exposure could include direct observations by others, birth records that may note admission of maternal alcohol use or maternal blood alcohol records, or history of alcohol-related events (such as driving under the influence or alcohol abuse treatment) during the pregnancy. The diagnosis of ARBD, ARND, or the newly-defined ND-PAE does require confirmed maternal alcohol use at any time during the pregnancy.

### Diagnostic Approach

Pediatricians can diagnose FAS when patients meet the facial, growth, CNS, and alcohol exposure criteria established by the CDC. The American Academy of Pediatrics (AAP) developed a schema in collaboration with the CDC for early and streamlined identification of FASD in the medical home. The AAP recommends

that all children be screened for developmental and growth concerns in the context of the well child evaluation. In addition, a history of prenatal alcohol exposure and other risk factors should be sought as part of the comprehensive patient history. The recommended diagnostic algorithm (Figure 250-3), available as part of the AAP FASD Toolkit, suggests that any child with FASD signs or symptoms, risk factors for FASD (particularly known/suspected maternal alcohol or other substance use; sibling with FAS/FASD; child was adopted or ever in the foster care system), or any parental concern for FASD should prompt additional evaluation by the pediatrician for CNS abnormalities, growth deficits, or characteristic facial features. Fetal alcohol syndrome can be diagnosed by the pediatrician if growth, facial, and CNS features characteristic of FAS are present in addition to known prenatal alcohol exposure.

Recognition of CNS features of FAS by the physician requires familiarity with how the neurobehavioral features of the FASDs can manifest at different ages. Infants and toddlers may have difficulty with self-soothing and be prone to over-stimulation. Poor feeding is commonly seen in young infants with FAS. Sleep problems, difficulties with language comprehension, and poor problem solving abilities may emerge in young childhood. Older, school-age children are more likely to present with specific learning disabilities, poor social skills (social immaturity, lack of social boundaries), and poor adaptive skills.

Facial characteristics of FASD often change over time, and may become less apparent as the child approaches adulthood. For this reason, review of photographs from early childhood may aid the physician in the diagnostic process.

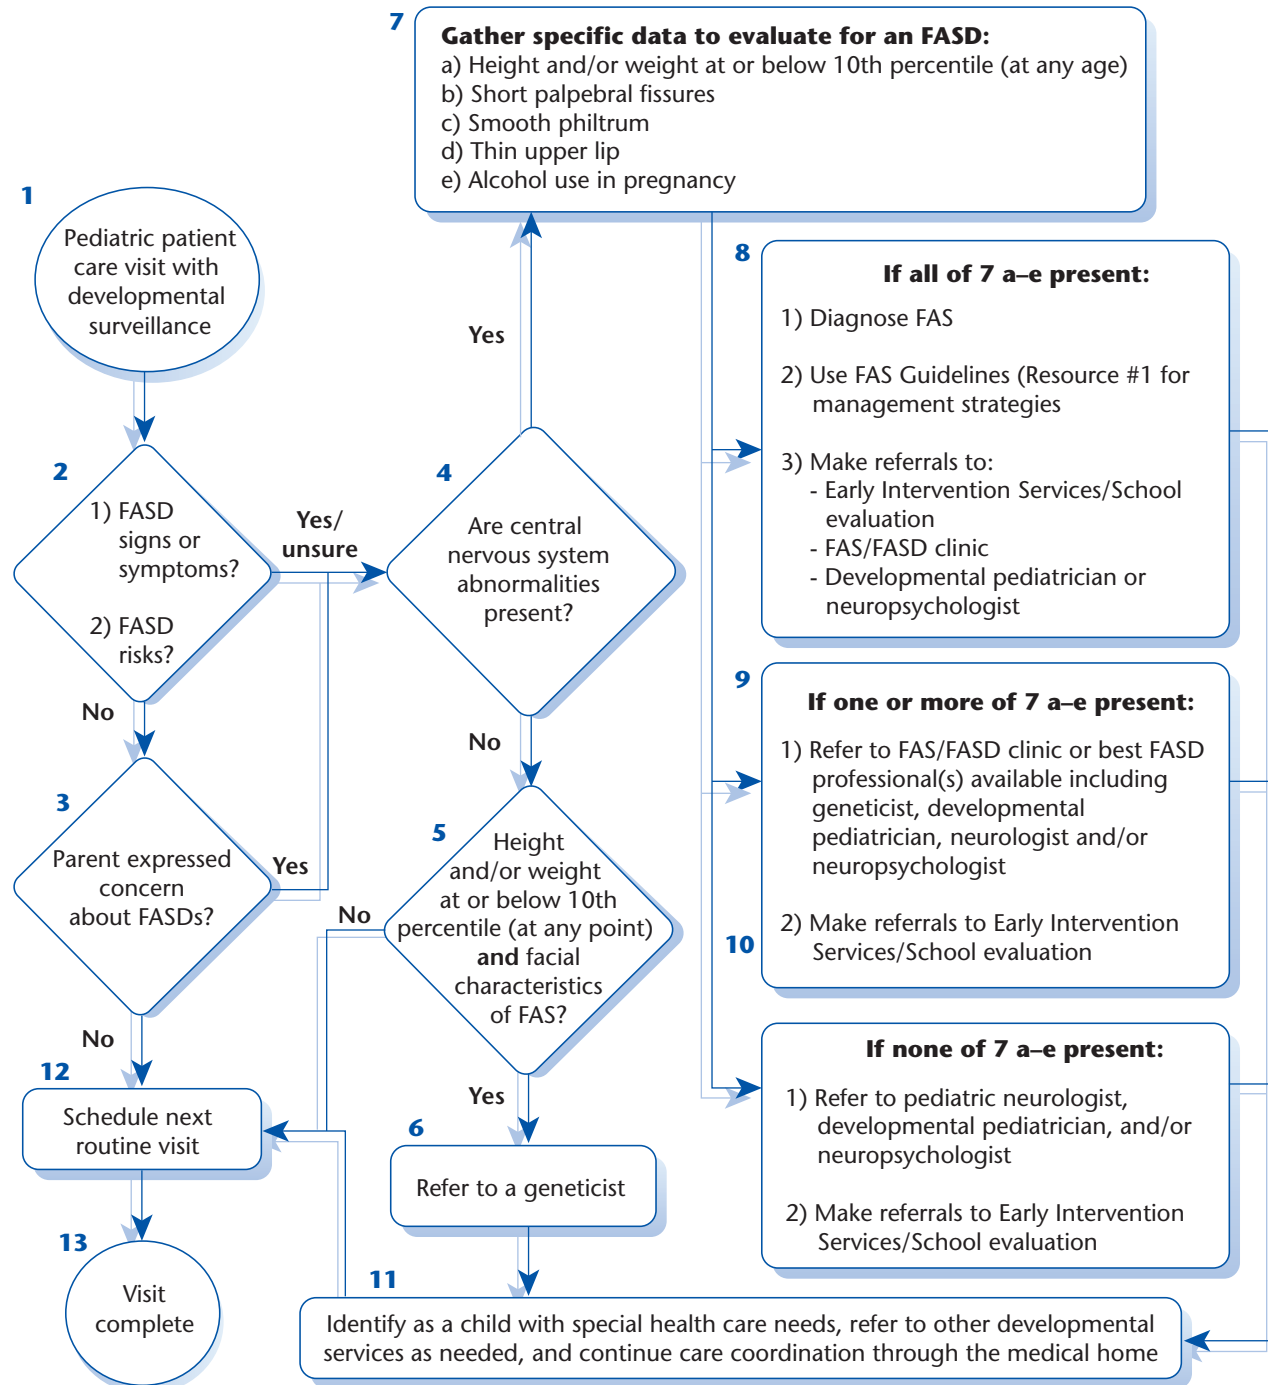

Referrals to specialists for further diagnostic investigations are indicated in certain circumstances:

1. If the child has growth restriction or any dysmorphic facial features, but no documented CNS abnormalities, referral to a geneticist is indicated for evaluation for possible alternate diagnoses.
2. If the child has CNS abnormalities but does not fulfill all the other facial, growth, and alcohol exposure criteria for FAS, referral to a FAS/FASD clinic or other appropriate specialist(s) (which may include a neurologist, geneticist, developmental pediatrician, or neuropsychologist) is indicated.
3. Referral to Early Intervention or school-based developmental services is warranted in any child with evidence of CNS abnormalities.

### Imaging and Diagnostic Studies

Imaging and other diagnostic or laboratory studies are not routinely indicated in individuals with FASD. However, intracranial imaging (ultrasound, computed tomography, or magnetic resonance imaging) may be performed in children because of the presence of microcephaly, seizures, or severe intellectual deficits. Results from neuroimaging studies can help support the diagnosis of FASD if clinically significant structural brain abnormalities are identified. Electroencephalograms may be performed when there is clinical suspicion of seizures. If there is a question of an alternate genetic diagnosis (see Differential Diagnosis),

**Figure 250-3** Algorithm for evaluation of fetal alcohol syndrome and fetal alcohol spectrum disorders within the medical home. FAS, fetal alcohol syndrome; FASD, fetal alcohol spectrum disorders. (From American Academy of Pediatrics. *Fetal Alcohol Spectrum Disorders Program* [www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/fetal-alcohol-spectrum-disorders-toolkit/Pages/Algorithm-for-Evaluation.aspx].)

diagnostic laboratory studies such as molecular genetic testing may be indicated to exclude other diagnoses with overlapping features. Neuropsychological testing is often needed not only to establish the presence of functional CNS deficits, but also to direct management (see Treatment Approach).

### Differential Diagnosis

The individual facial and other physical features that are characteristic of FASD are not unique and may overlap with those seen in a number of other teratogenic and genetic syndromes (Table 250-1 and Table 250-2). However, the combination of 3 facial features

**Table 250-1** Selected Differential Diagnosis for Individual Features Associated With FASD

FEATURE	ASSOCIATED SYNDROMES (OTHER THAN FASD)
Smooth philtrum	Touline embryopathy Maternal phenylketonuria effects Floating-Harbor syndrome X-linked Opitz G/BBB syndrome Geleophysic dysplasia Williams syndrome
Thin upper lip	Maternal phenylketonuria effects Touline embryopathy Cornelia de Lange syndrome Miller-Dieker syndrome Fetal valproate effects
Short palpebral fissures	Maternal phenylketonuria effects Touline embryopathy Dubowitz syndrome FG syndrome X-linked Opitz G/BBB syndrome Williams syndrome Feingold syndrome
Neurobehavioral features	22q11.2 deletion syndrome (DiGeorge syndrome, Velocardiofacial syndrome) Fragile X syndrome Turner syndrome 16p11.2 deletion syndrome 10p deletion syndrome
Pre- and postnatal growth delay	Associated with many chromosomal and single gene syndromes (too numerous to list)

FASD, fetal alcohol spectrum disorders.

(smooth philtrum, thin vermilion border, and small palpebral fissures) is more than 95% specific to FAS and prenatal alcohol exposure. Teratogenic syndromes that most closely overlap with the features seen in FASD include fetal valproate syndrome, maternal phenylketonuria effects, and toluene embryopathy. Some of the facial features commonly seen in FASD can also occur in a wide range of specific single-gene syndromes or chromosome abnormalities. Growth restriction and CNS abnormalities are common in many teratogenic and genetic syndromes. The presence or absence of other associated dysmorphisms can often help the physician formulate an appropriate differential diagnosis. In some cases, specific chromosomal or single-gene testing may be indicated to evaluate for alternate diagnoses. Prenatal alcohol exposure and genetic or other teratogenic syndromes may co-occur in some children, and may further complicate diagnosis. Referral to a geneticist is helpful in cases where all of the facial, growth and CNS features are not present,

or where the child has additional dysmorphisms that are atypical for FASD.

## TREATMENT APPROACH

An early and accurate diagnosis of FASD, where possible, is the first step in treatment. Studies of individuals with FASD and the effect their disorder has on their lives suggest that making an early diagnosis of FASD (ie, before age 6) is associated with a more favorable outcome and lower prevalence of secondary disabilities. Once a diagnosis of FASD is established, by either the pediatrician, an FASD diagnostic clinic, or the pediatrician in collaboration with other specialists (in those children who have features of FAS but do not fulfill the strict criteria for a FAS diagnosis), involvement of other specialists is often needed to manage the multiple medical, developmental, and psychological needs of the child. The AAP FASD Toolkit includes lists of resources for parents, educators, and physicians, including informational handouts, example care plans, and referrals to outside agencies. Additional resources for parents and physicians can also be found through the National Organization for Fetal Alcohol Syndrome ([www.nofas.org](http://www.nofas.org)). Patients who have a diagnostic evaluation in a multidisciplinary FASD diagnostic clinic will typically be seen by multiple specialists, which could include developmental pediatricians, neurologists, geneticists, social workers, physical and occupational therapists, speech-language pathologists, and psychologists/neuropsychologists. Pediatricians may choose to refer their patients to any of these specialists individually, based upon the child's specific needs.

A full assessment of a child's medical needs should be made and updated frequently by the pediatrician. Poor growth is common, and this may warrant careful monitoring of growth parameters or evaluation by a nutritionist. Children should be screened periodically for potential vision, hearing, and sleep difficulties, which occur with increased frequency in individuals prenatally exposed to alcohol. In infants or children for whom clinical history or physical examination suggests the possibility of cardiac, renal, or spinal (such as tethered cord) anomalies, specific imaging studies may be indicated for diagnosis.

Nearly all children with FASD can benefit from developmental assessment, through either early intervention services (before age 3), the school system (after age 3), or a neuropsychologist, psychologist, or developmental pediatrician. Proper neuropsychological assessment allows the child's specific educational and behavioral needs to be more precisely defined, which can be invaluable for educators. Assessment through the school district for children aged 3 and older should routinely be requested by the pediatrician or family in order to ascertain that the child is receiving educational supports. All children with a diagnosis of FAS qualify for services under the Individuals with Disability Education Act. It is important to note that while many children with FASD have IQ or other developmental quotients that fall in the normal range, specific deficits in memory, executive functioning, behavior regulation, or other functional CNS

**Table 250-2** Differential Diagnosis of FASD and Distinguishing Features

CONDITION	OVERLAPPING FEATURES WITH FASD	DISTINGUISHING FEATURES FROM FASD
22q11.2 deletion syndrome (DiGeorge/Velocardiofacial syndrome)	Ptosis, cardiac defects (much more common in the 22q11 deletion), learning difficulties, speech delay, short stature, short palpebral fissures (occasionally)	Palatal defects, immune dysfunction, hypocalcemia; smooth philtrum and thin upper lip not typically seen
Dubowitz syndrome	Growth delay (prenatal onset), microcephaly, short palpebral fissures, ptosis	Eczema; high-pitched, hoarse cry; genital anomalies in males; syndactyly and other limb anomalies
Maternal phenylketonuria effects	Microcephaly, short palpebral fissures, long and smooth philtrum, thin upper lip	History of phenylketonuria in mother; intellectual disability is typically severe; rounded facies; short, upturned nose
Cornelia de Lange syndrome	Pre- and postnatal growth delay, thin upper lip	Synophrys, long eyelashes, high arched palate, limb anomalies
Toulene embryopathy	Short palpebral fissures, smooth philtrum, thin upper lip	Large anterior fontanelle, micrognathia, bifrontal narrowing, downturned corners of the mouth
Floating-Harbor syndrome	Short stature, smooth philtrum, thin lips, ADHD, learning disabilities	Long nose with narrow bridge, full tip, and an overhanging columella; triangular facies; deeply-set eyes; philtrum is usually short
Feingold syndrome	Short stature, microcephaly, short palpebral fissures, cardiac defects, learning disabilities	Gastrointestinal atresia, finger/toe anomalies (syndactyly, brachymesophalangy)
Fetal valproate effects	Epicanthal folds, thin upper lip, long and smooth philtrum, variable learning disabilities	Tall forehead, trigonocephaly, bifrontal narrowing, infraorbital creases, neural tube defects
Geleophysic dysplasia	Thin upper lip, long and smooth philtrum, short stature	Round and full face, coarsening of facial features over time, thick skin, joint contractures
Miller-Dieker syndrome	Thin upper lip	Vertical ridging and furrowing in the central forehead, bitemporal narrowing, severe neurologic features (seizures, intellectual disability)
FG syndrome	Short palpebral fissures, short stature	Macrocephaly, tall forehead, downward-slanting palpebral fissures, small ears, constipation
X-linked Opitz G/BBB syndrome	Learning disabilities, microcephaly, smooth philtrum, short palpebral fissures	Prominent forehead, widow's peak, cleft lip/palate, laryngotracheoesophageal defects, genital anomalies
Fragile X syndrome	ADHD, learning disabilities	Frequent autism, more severe intellectual disability (in males), long face, prominent ears, joint laxity, macro-orchidism
Turner syndrome	ADHD, learning disabilities, short stature	Females only; does not share craniofacial features with FASD; ovarian dysgenesis, cardiac defects (aorta coarctation, bicuspid aortic valve), short neck, low posterior hairline, broad chest

ADHD, attention-deficit/hyperactivity disorder; FASD, fetal alcohol spectrum disorders.

Adapted from Bertrand J, Floyd RL, Weber MK, et al. *Fetal Alcohol Syndrome: Guidelines for Referral and Diagnosis*. Atlanta, GA: Centers for Disease Control and Prevention, 2004; and Senturias Y, Asamoah A. domains may impair their ability to succeed in school. The AAP FASD Toolkit lists evidence-based educational and behavioral interventions that are specific to parents and educators working with children with FASD (Table 250-3). These may include such strategies as highly structured and systematic teaching, use of visual reminders, and breaking down tasks into small, manageable units. Some children with FASD may need special education services that are similar to those provided to children with non-FASD-related intellectual or learning disabilities. Educational strategies should be tailored to the individual child's strengths and needs.

While no pharmaceutical interventions have yet been shown to directly alter the CNS abnormalities in children with FASD, use of specific medications, in addition to behavioral therapies, may be indicated for treatment of coexisting psychiatric or neurologic diagnoses. For example, use of stimulant medications may be warranted in children who also meet criteria for a diagnosis of ADHD, and children with seizures are often treated with antiepileptic medications.

Parental counseling regarding the diagnosis of FASD is an important component of its management. The diagnosis should be discussed with the foster, adoptive, or biological family in a nonjudgmental

**Table 250-3 Evidence-based Educational and Behavioral Interventions Specific for FASD**

PROGRAM	OVERVIEW	OUTCOMES
Math Interactive Learning Experience (MILE), Emory University, GA	6-week mathematics learning program providing an active learning approach for children; workshops for caregivers providing information on FASD and learning strategies	Improved math skills and decreased problem behaviors
Good Buddies, UCLA, Los Angeles, CA	12 weekly separate sessions for parents and children, providing social skills training and education about FASD	Improved parent knowledge about FASD; for children, there was greater social skills knowledge, improvement in social skills, and decrease in problem behaviors following the intervention
Parents and Children Together (PACT), Children's Research Triangle, Chicago, IL	12-week program of weekly neurocognitive habilitation group therapy sessions; concurrent parent education group	Improved executive functioning and self-regulation skills amongst children
Families Moving Forward (FMF), University of Washington, Seattle, WA	In-home training program (16 sessions over 9–11 months) providing education and support to families	Improved caregiver comfort and knowledge about FASDs; improved problem behaviors
Parent-Child Interaction Therapy, University of Oklahoma	14-week program in which caregivers are provided with live, coached practice of parenting skills	Improved problem behaviors in children and decreased parent stress

Atlanta, GA: Centers for Disease Control and Prevention, 2004.

manner, explaining the basis for the diagnosis, the spectrum of signs and symptoms, and the need for FASD-specific interventions. Emphasis should be placed on using the diagnosis as a tool to better understand the child's medical, developmental, and behavioral needs, and to direct medical and educational management. Without focusing on assigning blame, parents should be educated about the underlying cause for FASD; if appropriate, the biological mother may be offered referral to counseling or alcohol abuse treatment services. In addition, there should be an assessment of the parents' ability to provide safe and appropriate care for the child, which may require referral for a formal evaluation by a social worker or psychologist. In cases where the family unit is severely dysfunctional, alternative placement of the child may be considered. Family counseling may be indicated.

Because no single treatment plan is applicable to all children with FASD, the pediatrician's main role is frequently that of care coordinator, which is invaluable amongst children with complex and changing medical and neurocognitive needs. The pediatrician often facilitates clear communication between the child, his or her family, and other specialists or educators who are participating in the child's care. As the child ages, the primary care physician must also facilitate transition of care for the child, not only to an adult primary care physician, but also potentially to other subspecialists as he or she moves out of the pediatric realm.

## CONCLUSION

Fetal alcohol spectrum disorders represent a common, complex continuum of disorders resulting from prenatal exposure to alcohol. Pediatricians should be

attentive to the signs, symptoms, and risk factors that suggest a possible diagnosis of FASD. Well-defined criteria allow the diagnosis of FAS in children who manifest the characteristic facial, growth, and CNS features and have known or suspected prenatal alcohol exposure. However, diagnosis of individuals who were prenatally exposed to alcohol but do not have all of the cardinal features of FAS may be more problematic, and involvement of other specialists or referral to FASD diagnostic centers may be needed. The early and accurate diagnosis of FASD allows targeted medical and especially educational interventions that can improve the long-term outcome of children with FASD. The AAP FASD Toolkit includes a diagnostic algorithm, and can assist pediatricians in both the diagnostic and referral process. Physicians should also be aware of the potential differential diagnoses for FASD and make referrals to other diagnosticians (geneticists, neurologists, psychologists, etc.) as appropriate.

## WHEN TO REFER

- Diagnostic evaluation (if the child does not meet strict criteria for FAS or if an alternate genetic diagnosis is suspected)
- Neurologic evaluation (if focal neurologic signs or seizure disorder are present or suspected)
- Neuropsychological or other developmental testing
- Significant social and family issues
- Nutrition evaluation if significant growth disturbance
- Pharmacologic management of co-existing psychological disorders

**WHEN TO ADMIT**

The typical management of a child with FASD does not require admission to a medical or psychiatric hospital. However, indications for admission could include symptoms related to any of the mental health or behavioral conditions that could co exist with FASD, refractory seizures or initial seizure work-up and management, or evaluation of severe growth failure.

**Chapter 251****FOREIGN BODIES OF THE EAR, NOSE, AIRWAY, AND ESOPHAGUS**

Catherine C. Skae, MD; Sanjay R. Parikh, MD

Foreign bodies of the ear, nose, and respiratory and digestive tracts are a common problem among children, particularly those younger than 5 years. Children are at risk as soon as the pincer grasp is achieved, around 9 months of age; the risk may be present sooner if they have older siblings. The scope of the problem was first underscored by National Safety Council data in 1969, which showed that more children died at home from accidental foreign-body ingestion or aspiration than from any other cause. By 1998, foreign-body aspiration and asphyxiation was the fourth-leading cause of accidental death in the home among children younger than 5 years. National Safety Council data from 2005 to 2006 reveal that 133 deaths per 100,000 population in children from birth to 4 years were caused by choking defined as suffocation by inhalation or ingestion of food or other objects. There has been no improvement, as this category continues to be the fourth leading cause of death in children younger than 5 years. The mortality rate stayed the same, according to the National Safety Council's Injury Facts, 2014 edition. From 2005 to 2010, international cases were collected from 70 centers in 32 countries and registered in the Susy Safe Project Database, into which 17,205 foreign body injuries in children aged 0 to 14 years were entered. Seven percent of children required admission to the hospital, and complications were seen in 8.9%.

The severity of the problems caused by the presence of a foreign body depends on the site, composition, and duration of time in the body. Removal of a foreign body is not usually an emergency, unless the airway is compromised or the object is a battery that might cause liquefaction necrosis. The use of button batteries is increasing in small electronics, remote control devices, watches, toys, and hearing aids. In 2009, the American Association of Poison Control Centers listed disk batteries as the most common cause of fatal ingestions in children younger than 5 years. There was a 6.7-fold increase in major or fatal outcomes between 1985 and 2009. In addition, there has been an increase in magnet ingestions in children. In one series of magnet ingestions in children presenting to emergency departments, the incidence of emergency department

(ED) visits increased 8.5-fold from 2002 to 2011. Removal of any foreign body should be attempted only if the physician has appropriate sedation or anesthesia, proper instrumentation and illumination and, most important, ability. Attempts to remove the foreign body without these elements may aggravate the problem and jeopardize the child's well-being.

## FOREIGN BODIES OF THE EAR

Foreign bodies of the external auditory canal are most common among children between 2 and 4 years of age. They can include food, insects, toys, buttons, pieces of crayons, pencil erasers, button-shaped batteries, and jewelry. Accidental entry of a foreign object through placement in the external auditory canal, either by the child or a companion, can occur during play. Insects also can fly or crawl into the ear canal. Some experts suggest that children who have chronic external otitis or itching are more likely than healthy children to place objects in their ear canal. Earrings can become embedded in the auricle when a chronic infection of the pierced site is followed by overgrowth of granulation tissue. The use of a spring-loaded gun to pierce ears has resulted in numerous cases of embedded earrings as well.

Inert substances, such as plastic, that are not obstructing the canal and are not abutting the tympanic membrane may not cause symptoms. Insects tend to incite local irritation, causing discomfort, erythema, and occasionally drainage. Food matter also may cause local inflammation that often leads to local pain and itching. Objects that touch the tympanic membrane cause pain, particularly with movement of the drum, as when swallowing. If the entire canal is obstructed, then hearing will likely be decreased.

### History and Physical Examination

Usually, eliciting a history of placing an object in the ear canal is difficult because most children are reluctant to admit to this activity. If insertion is not witnessed, then some foreign bodies may go undetected for extended periods. Findings depend on the depth of the foreign object within the external auditory canal, the nature and composition of the object, and its duration in the canal. Children may complain of ear pain, discomfort, bleeding, discharge, an odor, aural fullness, hearing loss, nausea, vomiting, coughing, tearing, or dizziness.

Several reports have been issued on button-size alkaline batteries in the ear canal that may leak battery alkali, causing a severe local tissue reaction or destruction, with pain, swelling, and discharge. This foreign body should be handled expeditiously to prevent serious injury to the canal, tympanic membrane, or middle ear.

When the history indicates a small foreign body but it cannot be visualized on examination, it may be lodged anteriorly in the tympanic sulcus. Instillation of water to fill the medial half of the external canal may act as a concave lens, allowing visualization of the tympanic sulcus. In a patient who has a small, narrow, or swollen external ear canal, microscopic evaluation will aid in visualization. Physicians should check the other ear for foreign bodies as well.

## Management

### Nonurgent Situations

Aural foreign bodies may be removed by irrigation, suction, or instrumentation. Nonreactive foreign bodies that do not occlude the external canal completely or impinge on the tympanic membrane do not present an emergency. These foreign bodies can be removed with various instruments; the most useful will depend on the shape and composition of the object. In many cases, Frazier tip suction, alligator forceps, or a right-angle hook may be used to retrieve the object. The hook is used by passing it beyond the object, hooking it from behind, and gently pulling it out. Gentle irrigation also may be used on nonabsorbable substances, provided the tympanic membrane can be visualized and is intact and no evidence of inflammation of the external canal exists. Food matter tends to swell when water is applied, making removal difficult. Irrigation is accomplished using an 18-gauge catheter attached to a 10- to 20-mL syringe. The flow of fluid should be directed around the retained object, allowing back-pressure to force the object out of the canal. Fluids should be warmed to avoid irritation of the labyrinths. A nonperforated tympanic membrane must be visualized before irrigation. Using a syringe in this way is an effective and easy way to remove foreign bodies. The pressure generated by a 14- or 16-gauge cannula and a 20-mL syringe is well below the pressure required to burst a tympanic membrane.

Management of embedded earrings includes local anesthesia, with an incision made for removal of the earring. Oral and intravenous antibiotics are also used for presence of infection or cellulitis.

### Urgent Situations

In older children who are cooperative, a local anesthetic injected with a small-gauge needle into the skin lining the external canal may allow complete removal of the foreign body and subsequent examination. For younger children, or for those who are uncooperative, general anesthesia may be necessary and is certainly preferable to traumatic removal if a child is unable to cooperate or cannot be restrained adequately.

When the tympanic membrane cannot be visualized, or if evidence exists of inflammation or injury to the external canal, then the foreign body should be removed immediately. Expeditious removal is particularly important with an alkaline battery, because tympanic membrane perforations have been reported within only 8 hours of entry. Magnets may be helpful in removing metallic objects such as batteries or metal beads.

### Insects

Insects should be killed before removal by instilling water, mineral oil, or topical lidocaine into the external canal. Extraction with suction or alligator forceps may then be undertaken.

### Postextraction Care

After any foreign body is removed, the external canal and tympanic membrane should be thoroughly inspected. If the external auditory canal seems infected or irritated, then topical antibiotic otic drops with

steroids may be instilled. The affected ear should be protected from water until it has healed completely.

Consultation with an otolaryngologist should be requested if the object cannot be removed or if perforation of the tympanic membrane is suspected. Schulze studied 698 consecutive cases of pediatric external auditory canal foreign bodies. Attempts under direct visualization by ED physicians had lower success rates with removing spherical objects, objects touching the tympanic membrane, and objects in the canal for more than 24 hours. The physicians concluded that these cases should be referred directly to otolaryngologists for otomicroscopic removal.

### Complications

Complications can be caused by the foreign body or by traumatic removal. Laceration or inflammation of the external canal is not usually serious and resolves with instillation of liquid analgesics and antibiotics. Perforations of the tympanic membrane require careful inspection to ensure that a flap of the membrane has not folded into the middle ear leading to a permanent perforation or a cholesteatoma. Similarly, when the tympanic membrane is not intact, the middle ear space can become contaminated, and otitis media can develop. Balbani et al reviewed 93 cases of foreign bodies in the ear and found that all 12 complications (11 canal lacerations and 1 tympanic membrane perforation) occurred in patients who had undergone previous attempts at removal. Engelsma reported a case of impacted foreign body following 2 attempts at removal that required surgical widening of the canal before extraction.

If safely removing a foreign object from the ear canal is not possible, if the tympanic membrane may have been injured by either the foreign body or its removal, or if hearing loss, nystagmus, vertigo, cranial nerve deficits, or deep-seated infection occurs, then the patient must be referred to an otolaryngologist.

## FOREIGN BODIES OF THE NOSE

Foreign bodies in the nose are typically soft, such as tissue paper, eraser material, or clay; however, they can also be hard, as with a bead, pebble, or piece of candy. The Nationwide Electronic Injury Surveillance System (NEISS) was evaluated for ED visits and found jewelry beads to be the most numerous. Occasionally a foreign object enters the nose accidentally while the child is attempting to sniff or smell it. The frequency has been noted to increase during the summer and Christmas, when toy sales increase. In addition, with increasing use of magnetic body jewelry, there is the problem of magnets being accidentally stuck to each other on both sides of the nasal septum and causing tissue damage.

Children will usually not admit to placing foreign bodies in the nose. The most common symptom of a foreign body in the nose is unilateral nasal discharge that is usually foul smelling. In fact, a unilateral nasal discharge in a young child should be considered evidence of a foreign body until proved otherwise. Occasionally, epistaxis is the presenting symptom. When an alkaline disk battery is lodged in the nose, the

symptoms may be acute. Tissue damage can occur through 3 mechanisms: electrical burn, liquefaction necrosis (from sodium hydroxide), and pressure necrosis.

The differential diagnosis of foreign bodies in the nose includes suppurative rhinitis, adenoiditis, sinusitis, and nasal or nasopharyngeal tumors. Nasal polyps also may cause unilateral nasal discharge, and in a young child, the diagnosis of cystic fibrosis must be ruled out.

### History and Physical Examination

If possible, the anterior nasal cavities should be examined with a nasal speculum and suction. The key to any evaluation is powerful illumination.

### Management

Nasal foreign bodies should be removed as quickly as possible, particularly in the case of an alkaline battery, which can cause severe local inflammation, with tissue damage occurring within 1 hour of placement. When an alkaline disk battery is in the nasal cavity, saline irrigation should be avoided because it can cause further tissue damage. Young children are averse to nasal instrumentation, and removing a nasal foreign body requires some degree of cooperation or restraint. Thus, sedation or general anesthesia may be advised. Topical application of a vasoconstrictor agent (eg, oxymetazoline, phenylephrine) in conjunction with removal of secretions by a small suction tip helps visualize the foreign object, particularly an object lodged in the middle or posterior nasal cavity. Use of an endoscope may enhance the ability to visualize this region. Most items are retrievable using grasping instruments such as straight forceps and mosquito clamps. Other methods include suction, irrigation, and adhesives. A foreign body that has remained in the nose for a long time may become calcified and form a rhinolith. Removing a rhinolith is often difficult and bloody.

Radiographs may be helpful if the object is radiopaque or has become calcified. An incidental finding of a nasal foreign body on a routine dental radiograph examination has been reported. US toy manufacturers are required by law to make toy parts radiopaque, a regulation that proves quite valuable when a physician is looking for foreign objects in the nasal cavity or in any part of the upper aerodigestive tract. However, toys and toy parts manufactured outside the United States do not have to conform to this regulation. In their review of children who had nasal foreign bodies, Tong et al reported that 28 of 71 (39%) radiographs demonstrated a foreign body.

Foreign-body removal using pepper to induce a sneeze while the uninvolved nostril is occluded or blowing in the child's mouth while the contralateral nostril is held shut is not suggested (although Cook, et al found an overall success rate of 59.9% for the "mother's kiss"). In a more controlled fashion, nebulized epinephrine together with nose blowing has been reported to expel nasal foreign bodies successfully. Ambu-bag insufflation of the mouth with the patient in Trendelenburg position has also been described. Another method of removal involves using a

Fogarty or a small Foley catheter. The catheter is placed beyond the foreign body into the posterior portion of the nasal cavity or nasopharynx and then inflated with 2 to 3 mL of saline solution. The catheter is then drawn gently forward and out of the nose, expelling the object. The danger with this technique is that the foreign object may be dislodged by pushing it posteriorly into the nasopharynx, which may lead to aspiration of the object.

Soft, friable objects can usually be removed with a Frazier tip suction device. If the foreign body is firm and flat or has an edge, then it may be removed by using a nasal bayonet or Hartmann or alligator forceps. A wire loop may be placed beyond the foreign body that is spherical and removed by pulling it forward. After removal, local inflammation exhibited by bloody or purulent oozing may be controlled with saline nose drops and an antibacterial ointment such as bacitracin or mupirocin. Sterile water should be used in place of saline if the foreign object removed was an alkaline battery.

For the situation in which magnets are stuck to each other on both sides of the nasal septum, Yeh and Robertson report using 2 cardiac pacemaker magnets and 2 forceps to remove them.

In addition, physicians should consider a second foreign body in the nose or elsewhere.

### Complications

Complications of nasal foreign bodies include epistaxis, local infection, inflammation, and nasal septal perforation. Occasionally a scar band, or synechia, may form between the turbinate and septum. Scar bands can be prevented by placing a splint made of Gelfilm or Silastic over the raw, exposed area. Nasal septal perforation has been reported. Obstruction of a sinus ostium by a foreign object may lead to the development of sinusitis, which typically causes pain and tenderness over the affected sinus or clouding and an air-fluid level on radiograph. Treatment includes oral antibiotics and nasal decongestant drops. Aspiration of a nasal foreign body can be prevented in most cases by prompt and skilled removal.

## FOREIGN BODIES OF THE AIRWAY

As of 2011, foreign body inhalation or ingestion account for 6% of all unintentional deaths in children ages 1 to 4 years. In 1 study, 184 patients younger than 16 years with a tentative diagnoses of foreign body aspiration were analyzed. The most frequently aspirated items were shelled nuts and seeds, such as sunflower seeds, pistachios, and hazelnuts. In a retrospective review of 2,165 autopsy cases from Great Ormond Street Hospital for Children, grapes were the foreign bodies involved in 4 out of 10 cases. The incidence of death declines rapidly among those older than age 5. Increased parental awareness of the risks of leaving small objects within the reach of young children and consumer education have been important in diminishing this hazard. In addition, lifesaving techniques, such as the Heimlich maneuver, that can be performed by people who are not health care workers accounts for a higher survival rate.

Complete airway obstruction is generally caused by globular foods such as hot dogs, nuts, candies, and grapes, or by toys or latex balloons. With regard to foreign-body impaction, the airway can be divided into 3 segments: larynx, trachea, and bronchial tree. Lima reviewed all airway foreign body admissions to a pediatric hospital from 1980 through 1987. Of the 91 cases, 11 involved a foreign body lodged in the larynx. Of these 11 patients, 5 died, and 3 suffered anoxic encephalopathy.

### Etiology

Curiosity or boredom may lead young children to put objects in their mouth. Infants in particular will place almost anything they can handle into their mouths. A startle may cause inadvertent ingestion or aspiration. Lack of complete dentition, as well as lack of attention to chewing, allows large food particles to enter the posterior pharynx. Incomplete development of mouth and tongue coordination and the neuromuscular mechanism for swallowing in young children also may account for a greater incidence of foreign-body ingestion or aspiration. A positive association between the occurrence of upper respiratory tract infections and foreign body aspiration has been noted possibly stemming from the need for continuous mouth breathing. An upper respiratory tract infection interrupts a smooth breathing-swallowing pattern, leading to an increase in aspiration. Although this situation typically occurs in the younger child, some estimates indicate that 23% occur in children older than 5 years. In addition, there are increasing reports of blowgun dart aspirations in adolescent males. During the deep inhalation required to blow a dart, the vocal folds maximally abduct, creating an increased risk of aspiration.

### History and Physical Examination

When an object is aspirated into the respiratory tract, it initially produces a choking, gagging, coughing, or wheezing episode. This may be followed by an asymptomatic interval during which little evidence remains to suggest the presence of a foreign body.

Depending on the site of the foreign body in the airway, a patient may exhibit a spectrum of findings, ranging from an almost complete lack of symptoms to signs of complete airway obstruction. A high index of suspicion and knowledge of the many possible presentation scenarios are the best insurance against the hazards of missed or delayed diagnoses.

Laryngeal foreign bodies are likely to produce the most acute and dramatic presentation. Large objects that completely obstruct the airway may result in stridor, high-pitched wheezing, cough, dysphonia, or worse—aphonia and cyanosis. Children who have small, partly obstructing objects that allow adequate air exchange have cough, stridor, hoarseness, and pain or discomfort.

Tracheal foreign bodies are usually associated with cough and some degree of stridor or wheezing, and may produce an audible *slap* as the object moves from the carina to the glottis with respiration. Bronchial foreign bodies usually cause wheezing or coughing if they are partly obstructing, which is often misdiagnosed as asthma. With complete obstruction of a

bronchus, an initial asymptomatic period is followed by a postobstructive pneumonitis or bronchiectasis. Sharp objects such as pins or tacks may cause pain or hemoptysis.

### Imaging

If aspiration of a foreign body into the upper airway is suspected, then plain-film radiographs may be useful. For objects suspected of being lodged in the laryngeal inlet, radiographs of the upper trachea or esophageal inlet should be obtained if the child's condition permits. Bronchial foreign bodies may be suggested by some form of dynamic radiographic study, such as inspiratory-expiratory films, lateral decubitus films, or videofluoroscopy. These studies can demonstrate air-trapping in the affected lung.

### Management

Foreign bodies that completely obstruct the laryngeal inlet create a life-threatening emergency and should be expelled immediately by using the Heimlich maneuver (abdominal thrusts). For infants younger than 1 year, the American Academy of Pediatrics recommends 5 back blows in the head-down position followed by 5 chest thrusts in the supine position, in place of the Heimlich maneuver. Blind finger sweeps are dangerous and should be avoided. If the foreign body cannot be expelled, then a large-bore needle or angiocatheter (14 gauge) should be inserted into the cricothyroid space to allow some degree of ventilation until the patient can be taken to the operating room for removal of the object. Alternatively, if skilled personnel are present, then an emergency tracheotomy may be necessary. Partly obstructing laryngeal foreign bodies should be treated in a manner that prevents total obstruction of the airway; therefore, back blows and abdominal thrusts should not be used in these cases.

Tracheal and bronchial foreign bodies should be removed by a physician specifically trained for the task. This usually requires controlled endoscopic removal (a rigid scope is the standard for airway foreign bodies) in the operating room. This situation is not usually an emergency; therefore, adequate preparations can be made.

### Complications

Abdominal and chest thrusts may damage intraabdominal contents (eg, liver, spleen) and ribs, respectively. Therefore, these techniques should be used only in cases of complete airway obstruction that would otherwise cause certain death. Conversion of a partial airway obstruction to a complete obstruction can best be prevented by having skilled personnel retrieve the foreign body. Pneumonia was the most common complication in 127 cases of foreign body aspiration.

A bronchial foreign body that remains in place for an extended period may cause air trapping and irreversible bronchiectatic changes distal to the obstruction.

Prolonged or difficult instrumentation of the airway during removal of a foreign body can lead to laryngeal edema or injury, with obstructive symptoms. This situation may require a period of intubation after surgery. As an alternative, postoperative edema can sometimes be prevented by using steroids during and after surgery.

## FOREIGN BODIES INVOLVING THE ESOPHAGUS

Young children are inquisitive and tend to explore objects orally. The objects are then intentionally swallowed or accidentally ingested as the result of a startle. Coins, food, marbles, buttons, pins, tacks, jewelry, magnets, and batteries are a few of the numerous foreign bodies children have ingested. Coins are the most frequent esophageal foreign body in children younger than 10 years, and fish bones are the most common in children older than 10 years. Developmentally delayed children are at high risk, as are children who have undergone esophageal surgery and those who have a damaged esophagus from prior caustic ingestions. Modern button batteries are twice as large (20mm vs 10mm) and twice as powerful (3 V vs 1.5 V) as old batteries. These larger batteries are more likely to get stuck at areas of physiologic narrowing. There is a rising incidence of these injuries. There is increasing popularity of these batteries in remote controls, car key fobs, and toys.

The esophagus has 4 physiologic areas of narrowing: the cricopharyngeal sphincter, the aortic arch, the region of the left main bronchus, and the gastroesophageal sphincter. These areas correspond to the 4 most common sites of foreign body obstruction. The cricopharyngeus is the most common; the arch of the aortic region is the most dangerous. If the foreign body is lodged at the lower border of the cricopharyngeus muscle, then it will be visualized at the level of the clavicles on chest radiograph.

Physicians need to be aware that the incidence of magnet ingestions is increasing. In addition, there are more high-powered (neodymium) magnets available that are being marketed as desktop toys. The site of attraction between ingested magnets can cause serious mucosal injury and mortality.

### History and Physical Examination

The history of foreign-body ingestion is often not obtained, and most foreign bodies pass through the normal esophagus undetected. A swallowed or aspirated object can cause a respiratory emergency, no symptoms at all, or anything in between. Objects that do not pass freely initially stimulate the larynx and cause gagging and coughing. Subsequent symptoms depend on the size, composition, and nature of the foreign body. With young children, poor feeding or refusal to eat or drink, as well as increased drooling, are typical. When the esophagus is completely or almost completely obstructed, choking and vomiting occur. The duration of obstruction can affect the clinical presentation; that is, the longer a foreign object is present, the greater the tissue reaction and local inflammation will be. Thus, in the later stages, patients can have pain on swallowing, airway compromise, fever, and leukocytosis.

### Imaging

When a foreign body is suspected, posteroanterior and lateral chest radiographs, in addition to neck radiographs, are diagnostic if the object is radiopaque, such as a coin. If the foreign body is a coin, then it will

most often be oriented in a transverse position because the opening of the esophagus is widest in a transverse position. However, it could also be oriented in the sagittal orientation, a finding that supports a coin in the trachea. Lateral radiographs are also important to determine the location of the object as well as presence of air trapping. Contrast studies can be used when an esophageal foreign body that does not show on routine radiographs is strongly suspected. Button batteries have a 'double ring' or 'halo' appearance on plain radiograph.

Metal detectors have also been diagnostically useful to detect foreign bodies. They are relatively inexpensive, easy to use, and have no risk of radiation exposure.

### Management

An esophageal foreign body that is an alkaline button battery or magnet requires emergency management. Other foreign bodies do not usually require emergency measures, but should be removed as soon as possible after proper evaluation and preparation. In many instances, children will have eaten recently, and generally, experts recommend that an appropriate period pass before they are given general anesthesia. If the foreign body is corrosive, such as an alkaline button battery, then it should be removed emergently to prevent severe inflammation and potential perforation of the esophageal wall. Multiple magnets lodged in the hypopharynx or esophagus can rapidly cause pressure necrosis and deserve prompt management as well. If there is no history of esophageal disease and no respiratory compromise, 12 to 24 hours of expectant management for spontaneous passage could be considered.

Endoscopic removal under anesthesia by a trained expert is most commonly used. With rigid esophagoscopy, optical forceps are passed through the central channel for retrieval of the foreign body. This technique allows for direct visualization of the esophagus, its mucosa, and the foreign body. Removal with flexible endoscopy is also possible. Once the scope is passed, a variety of flexible graspers, forceps, baskets, and magnets can be passed through the instrument channel to retrieve the object. Generally, flexible endoscopic removal of esophageal foreign bodies is recommended, rather than rigid esophagoscopy. Other nonendoscopic techniques for removing an esophageal foreign body (eg, with a Foley or Fogarty catheter) are used and are safe and effective when used by experienced medical professionals in appropriate settings on appropriate patients.

All button battery ingestions should be reported by physicians: call the National Battery Ingestion Hotline (NBH) administered by the National Capital Poison Control Center 202-625-3333 or go to [www.poisn.org](http://www.poisn.org). United States Consumer Product Safety Commission.

### Complications

Perforation of the esophagus can result from the endoscopic procedure or may be caused by the foreign body itself, especially if it is sharp or caustic. Several

recent reports highlight the serious complications related to button batteries: mediastinitis, tracheoesophageal fistula, aortic rupture, spondylodiscitis, and death. Endoscopic removal is particularly dangerous with objects lodged at the level of the aortic arch. If an esophageal tear is suspected, then a radiographic gastrograffin swallow study will usually confirm or negate the suspicion.

Retropharyngeal abscess has been reported as the most common complication of a sharp esophageal foreign body, such as a fish bone. Foreign bodies that have been in the esophagus for long periods can also cause a stricture to develop. In these cases, a contrast study, computed tomography scan, or esophagoscopy also should be performed to aid in the diagnosis.

During anticipatory guidance, parents and caregivers should be instructed not to leave small objects or inappropriate food where a young child can reach them or give them to a young infant.

### WHEN TO REFER

- Airway compromise exists
- When a battery is involved
- When magnets are involved in the airway or esophagus
- If the child cannot be restrained adequately
- If an object cannot be removed
- Ear:
  - Tympanic membrane cannot be visualized or perforation is suspected
  - Object is touching the tympanic membrane
  - Object is spherical or in the canal for more than 24 hours
  - Hearing loss, nystagmus, vertigo, central nervous system deficits, or deep-seated infection exists
- Nose: if a rhinolith has formed
- Airway: for tracheal and bronchial foreign bodies
- Esophagus: for endoscopic removal if object is stuck or if perforation is suspected

### WHEN TO ADMIT

- Airway:
  - Prolonged or difficult instrumentation of the airway occurred during removal of the foreign body
  - Postoperative edema develops
- Esophagus: if the object is sharp, corrosive, or magnetic and irretrievable by endoscope

## Chapter 252 FRACTURES AND DISLOCATIONS

R. Scott Strahlman, MD

Physicians who care for children see scores of fractures and dislocations each year. A familiarity with the proper triage and management of injuries is essential so that the physician can feel comfortable managing an injury conservatively or referring to an orthopedic specialist. This chapter covers the pathophysiologic features, clinical assessment, and classification of fractures and dislocations and discusses some of the more common fractures and dislocations encountered in primary care.

### DEFINITIONS

A *fracture* is defined as a break or crack in a bone. The fracture may occur directly at the site of injury or indirectly when the break occurs at a site different from the applied force. Stress fractures result from recurrent trauma to a bone and often occur in athletes (eg, long-bone fractures in

distance runners). Pathologic fractures can occur without trauma or with minor trauma when a bone is weakened, as with osteogenesis imperfecta or a tumor.

A *dislocation* is defined as a malposition of bone ends that normally oppose each other within a joint. Dislocations are far less common in children than are fractures because a child's ligaments are quite strong compared with an adult's; with an injury, a bone will more likely break or a growth plate will more likely separate than a ligament will tear.

Broad generalizations can be made about the pathophysiologic features of childhood fractures. First, fractures in children heal more quickly than in adults. For example, a fractured clavicle in a 4-year-old may heal in as little as 3 weeks. Second, the remodeling that occurs in the healing of pediatric fractures often corrects residual bony deformities. Third, children's bones are resilient; they may bend instead of break, or they may break on 1 side only (a greenstick fracture). Fourth, a phenomenon called *overgrowth* occurs in pediatric long-bone fractures. Overgrowth is an accelerated growth rate of bony fragments during healing. Long-bone fractures are therefore often corrected with overriding of the broken ends to prevent length discrepancies with the uninjured side. Finally, the growth plate must be protected when treating children's fractures because a growth plate injury can result in the loss of growth potential.

### EVALUATION

Whenever a fracture or dislocation is suspected, an accurate history is essential. Historical details may provide clues about the mechanism of injury. The physician should find out how, where, and when the injury occurred and where any pain is located. A fall off of a skateboard or scooter increases suspicion for a forearm fracture. Does the parent or child report any loss of function in the affected limb? Does the history show acute or recurrent trauma?

A complete physical examination, including vital signs and a neurovascular assessment, is key to reveal signs of serious trauma and secondary sites of injury. Pulses should be normal. Sensation should be intact, and movement, even if limited by discomfort, should be present. Absence of pulses, sensation, or movement signifies a serious injury requiring immediate medical attention. The examiner should look carefully for any unnatural or deformed position of joints or limbs, pain on palpation or attempted movement, or swelling and discoloration. Crepitus can sometimes be elicited at a fracture site. Any of these findings should alert the physician to order imaging studies.

Radiography is a mainstay in the diagnosis of fractures and dislocations. Radiographs from 2 angles are indicated to delineate subtle fractures. To rule out a dislocation, including the joint above and below the injury is sometimes helpful; in many cases, obtaining a film of the unaffected side for a comparison view may be helpful. Stress fractures are often missed on radiography. If a stress fracture is suspected, then a magnetic resonance image or a radionuclide bone scan may be indicated. Occasionally, when injury to the growth plate is a concern, other imaging techniques such as computed tomography can be useful.

## CLASSIFICATION

Fractures may be classified according to their clinical appearance. A closed fracture has no break in the skin. With an open, or compound, fracture, a bone fragment is exposed to the air, increasing the risk for infection and injury to adjacent nerves and blood vessels. A hidden fracture causes slight pain and swelling but no obvious bone deformity. Radiographs are necessary to confirm the diagnosis. An obvious fracture or dislocation is easily seen, even with a cursory examination. Immediate medical attention is necessary.

Fractures also are classified by their anatomic location and according to their radiographic appearance. Breaks in the bone may be described by their appearance as transverse, oblique, or spiral. A torus or buckle or incomplete fracture most commonly occurs after injury to the forearm and radiographically shows a wrinkled-appearing break of the distal radius on just 1 side of the bone. A fracture is comminuted when the bone has 3 or more fragments. With an impacted fracture, the bone ends are compressed into each other.

Probably the most important classification system for fractures is the Salter-Harris system of describing injury to the growth plate (Figure 252-1). Growth or epiphyseal plate injuries occur only in childhood. They must be treated with care to protect a bone's growth potential. Approximately 15% of all childhood fractures involve the growth plate. In a Salter-Harris I fracture, the epiphysis is separated from the metaphysis without a true break in the bone. Radiographs are often normal, and the diagnosis is made based on the clinical picture: tenderness over the area of the growth plate. Growth is usually not disturbed. The treatment is immobilization by cast for approximately 3 weeks. The most common growth plate fracture is the type II fracture, in which a fragment of metaphyseal bone separates from the epiphysis. Closed reduction of the fracture is usually possible; with proper casting, growth is not disturbed. A Salter-Harris III fracture involves a growth plate injury through the epiphysis and involves the articular surface. Open repair of the

fracture in the operating room is indicated to align articular surfaces and preserve joint function. A Salter-Harris IV fracture extends across the growth plate, injuring both the epiphysis and the metaphysis. The fracture must be perfectly realigned to protect growth potential. In a Salter-Harris V fracture, the growth plate is compressed. The prognosis for preserving growth is poor in this case because of a crush injury to the growth plate.

Chip fractures that do not cause any direct injury to the growth plate are not usually included in the Salter-Harris classification system.

## MANAGEMENT

Fractures and dislocations should be splinted and immobilized immediately. For most fractures and dislocations, consultation with an orthopedic specialist is necessary. Most pediatric fractures respond to closed reduction by the orthopedist. Even some compound fractures can be managed nonoperatively. If the growth plate is affected, however, then open reduction in the operating room is performed. Close pediatric and orthopedic follow-up are always important. A child in a cast should be comfortable; if pain is persistent, or if color changes or sensory changes to the casted extremity occur, then the child needs re-evaluation and possibly requires recasting.

## COMMONLY ENCOUNTERED FRACTURES AND DISLOCATIONS

### Fractured Clavicle

A broken clavicle, or collarbone, is the most common pediatric fracture. It can occur at any time during childhood as a result of trauma. This fracture often occurs at birth when vaginal delivery is difficult. The incidence can be as high as 3.5% in babies delivered vaginally. Physical findings include decreased arm motion on the affected side, crepitus, and swelling at the fracture site. A radiographic or ultrasound study may be needed, if the diagnosis is in doubt, to confirm the diagnosis. If the condition is asymptomatic, then no treatment is needed; indeed, the diagnosis is often made after the fact, when a callus at the fracture site is noted at a well-baby visit. If the fracture causes pain or reduced arm movement, then immobilization of the arm on the affected side for 2 to 3 weeks is indicated. In older children, treatment requires splinting for 3 to 4 weeks in a simple sling. Figure-of-8 bandages have been found to be cumbersome and are no better than a sling. Most of the fracture's healing and realignment are spontaneous.

### Developmental Dysplasia of the Hip

The femoral head has a tendency to dislocate in as many as 5 of every 1,000 infants. This condition, formerly known as congenital hip dislocation, is termed *developmental dysplasia of the hip* (DDH). Because hip dysplasia is not always detected in the newborn period, children younger than 1 year should be examined for hip dislocation at every routine visit.

Although the exact cause is unknown, many factors contribute to DDH. The disorder may be related, in part, to abnormal intrauterine positioning and therefore is

**Figure 252-1** Salter-Harris classification of growth plate injuries. (See text for explanation.)

more common in breech deliveries and in infants delivered by cesarean section. DDH occurs in up to 23% of breech infants. The condition is 6 to 8 times more common in girls than in boys. Theories suggest that female fetuses are more sensitive to maternal hormones that can induce ligamentous laxity of the hip. DDH is 3 times more common on the left side than the right, and in approximately 20% of cases is bilateral. The tendency to occur more often on the left is believed to be the result of intrauterine positioning. Most fetuses are positioned left occiput anterior during the later stages of pregnancy. This position puts the left hip against the mother's spine, thereby putting additional pressure on the left hip to dislocate. A genetic predisposition also exists: the risk for DDH is increased when a positive family history of hip dislocation exists.

Radiographs are of limited value during the neonatal period in the diagnosis of developmental dysplasia of the hip. Therefore the physical examination is of utmost importance. The Ortolani test is used to detect a dislocated hip. With the baby laying supine, the hips and knees are flexed and the knees brought together. The examiner then places a hand on each of the baby's knees, with each middle finger over the greater trochanter and each thumb over the medial thigh. With gentle abduction of the knees, the dislocated femoral head will slip back into the acetabulum, and an audible or palpable *clunk* results. Notably, a hip *click* (without a *clunk* and without any movement of the femoral head) does not indicate a hip dislocation. The Barlow test is essentially the reverse of the Ortolani test: the femoral head can be felt slipping out of the acetabulum when the knees are brought back together. Both tests are important to perform because the Ortolani test pushes a dislocated hip *back into* the hip socket, and the Barlow test pushes a dislocatable hip *out of* the hip socket. An examiner may feel unusual laxity of the hip by pushing up and down on the thigh when the hips are flexed and adducted (sometimes called the *telescoping sign*). Older infants should be examined for limited hip abduction, asymmetry of the thigh skin folds, a limp when cruising or walking, and leg-length discrepancy. One way to determine leg-length discrepancy is the Galeazzi sign: With the infant lying supine, the examiner flexes the infant's thighs and brings the knees together. If one knee is higher than the other, then the Galeazzi sign is *positive*, and the possibility of a dislocated hip exists. If the diagnosis is in doubt, then an ultrasound study, and in infants older than 4 to 6 months a radiograph, will confirm or rule out a dysplastic hip. Treatment requires referral to an orthopedist for a harness or casting. Some newborns with mild DDH can be monitored with serial ultrasounds and do not require active intervention. Infants diagnosed before 6 months of age can be treated with a Pavlik harness, which is worn for up to 5 months. Infants diagnosed after 6 months of age, and infants in whom the harness was not successful, require casting and sometimes surgery. Treatment is more straightforward the earlier the diagnosis is made, which makes it imperative for the physician to assess for DDH at every routine pediatric visit. Because of the increased incidence of DDH in breech infants, it may be of benefit to do an initial screening

ultrasound of the hips in breech infants at birth, with a follow-up ultrasound at 6 weeks of age and a radiograph at 6 months of age to screen for DDH. There is growing evidence that tight swaddling may contribute to hip dysplasia in at-risk infants. It is therefore recommended that if babies are swaddled, their legs be left free to move so that the hips can remain flexed and abducted.

### Nursemaid's Elbow

*Nursemaid's elbow* is a common dislocation in pediatrics. The name derives from the fact that this dislocation occurred frequently during the 19th century in children under the care of nursemaids. It is a transient subluxation of the proximal radial head (Figure 252-2) caused by pulling or *yanking*, usually inadvertently, of a child's arm, often by a parent or caregiver. The annular ligament of the radial head becomes entrapped in the radiohumeral joint (see Figure 252-2). The condition usually occurs in children between 1 and 4 years of age. The child refuses to move the arm and keeps it flexed and pronated. Radiographs are rarely necessary; the history and characteristic posture of the child's arm confirm the diagnosis. The treatment, easily performed by the pediatrician, requires rapid, forceful supination of the forearm while pressure is placed over the proximal radial head, followed by extension then flexion of the elbow. Symptoms usually resolve within 30 minutes. The condition is sometimes recurrent, in which case great care must be taken when holding hands with the affected child, lest the child suddenly try to pull away.

### Child Abuse

Unfortunately, fractures and dislocations are all too commonly suggestive of child abuse (see Chapter 367, Physical Abuse and Neglect). Child abuse may be suspected when an unexplained injury occurs or when an inconsistency exists between the history and the physical findings in a childhood injury. The delay between the time of injury and the time that medical attention is sought may be unusually long. Multiple bruises may be noted on physical examination. If abuse is suspected, then a radiographic bone survey should be performed in younger children. Silent fractures, or multiple fractures in varying stages of healing, may be seen.

**Figure 252-2** Nursemaid's elbow.

When child abuse is suspected, child protective services and social services should be involved. If child protective services cannot respond in a reasonable time to make plans for the child's safety, the child may need to be hospitalized. The child may also need to be hospitalized for appropriate evaluation and orthopedic care. All practitioners of pediatric care have a moral and legal responsibility for detecting child abuse and reporting all suspected cases.

### Toddler's Fracture

Radiologists refer to a spiral fracture of the tibia as a *toddler's fracture* when the fracture occurs in a child younger than 6 years of age. Torsion of the foot creates a spiral break in the tibia. The trauma to the leg often is minor or unwitnessed; therefore, in many instances, no history of trauma can be found. Symptoms can be minimal; the child may be brought for medical attention only because of reluctance to bear weight on the affected leg. The physical examination is significant for tenderness over the affected area of the tibia. A diagnosis can be made with anteroposterior and lateral radiographs of the tibia-fibula, but the fracture is sometimes not evident on a radiograph for a few days. The physician therefore should not hesitate to repeat films on a child who has an unexplained limp that is not resolving spontaneously. Treatment requires immobilization in a cast for 3 to 4 weeks.

Because the signs and symptoms of a toddler's fracture can be subtle, the examiner should have a high index of suspicion in a child who has a limp or fails to bear weight. Because the cause of the fracture is often unexplained, child abuse is sometimes a consideration.

### Forearm Fractures

A forearm fracture is one of the most common fractures seen in a pediatric practice. The fracture occurs when a child falls, because of an innocent stumble or a sports-related fall, and stops the fall with an outstretched palm of the hand. Usually the fracture is located in the distal metaphysis of the radius. A fracture should be strongly suspected whenever there is a fall and there is localized tenderness in the distal radius (palmar side). It is important to order a radiograph in this situation. The typical radiographic appearance is an incomplete fracture, called a *torus* or *buckle fracture*. Although casting by an orthopedist is usually necessary for 3 to 4 weeks, mild fractures can sometimes be treated with splinting. When a fracture of the radius is more severe and causes angulation of the distal radius, it is referred to as a Colles fracture (named after the Irish doctor who first described this fracture in 1814). A Colles fracture requires realignment by the orthopedic surgeon followed by casting.

### Shoulder Dislocations

Shoulder dislocations are uncommon in children but increase in frequency during adolescence and are often sports-injury related (see Chapter 334, Sports Musculoskeletal Injuries). With a shoulder dislocation, there is usually anterior dislocation as a result of direct trauma to the shoulder. The anterior capsule of the shoulder is often damaged and may

predispose a child to recurrent dislocation. Radiographs may be necessary to rule out a fracture. Treatment consists of reducing the dislocation with gentle traction of the arm, downward and medially. Because shoulder dislocations are very painful, treatment may require sedation in an emergency department setting. After the dislocation is reduced, the shoulder is immobilized for 3 to 6 weeks, and then activities are slowly resumed, sometimes with the help of physical therapy. Referral to an orthopedic specialist is appropriate.

### WHEN TO REFER

- All dislocations and fractures not easily managed in a primary care setting, including displaced fractures needing reduction, intrarticular fractures, Salter-Harris III, IV, and V fractures require referral.
- Complicating factors such as compartment syndrome, vascular injury, open fracture, multiple trauma, and nerve injury require immediate referral.

### WHEN TO ADMIT

- Whenever child abuse is suspected or if the patient is not medically stable (ie, multiple injuries).

## Chapter 253

# FRAGILE X SYNDROME

Robert A. Saul, MD

## FOUNDATION

### Definition

Fragile X syndrome is an X-linked genetic condition characterized by trinucleotide repeats in the fragile X mental retardation 1 gene (*FMR1*) altering fragile X mental retardation protein (FMRP) expression. It is the most commonly inherited form of intellectual disability. Fragile X syndrome is one of the *FMR1*-related disorders—the other 2 being fragile X-associated tremor/ataxia syndrome (FXTAS) and primary ovarian insufficiency (POI). Males with fragile X syndrome can manifest significant developmental delay without obvious physical features early in childhood. Females can also be affected with usually milder developmental delay. The phenotype (physical and behavioral) can change over time.

FMRP plays an important role in protein synthesis regulation at the level of dendritic development at neural synapses. Abnormal dendrite development will lead to cognitive impairment, presumably because of abnormal synaptic function and plasticity. A unique feature of the fragile X syndrome is the nonclassical gene-disrupting alterations in protein expression caused by the trinucleotide repeat gene changes. Too many repeats in this region will lead to excess methylation in the promoter region of the gene, and FMRP protein production will decrease substantially. Rarely, a classic mutation of the gene can occur. Individuals with a normal number of repeats in their fragile X allele will have 5 to 44 CGG trinucleotide repeats in exon 1 of the gene. Individuals with an intermediate number of trinucleotide repeats (45 to 54) are typically unaffected, and individuals with 55 to 200 repeats are considered premutation carriers. This latter group is not usually at risk for intellectual disability, but women are at risk (as high as 20%) for POI (onset of menopause prior to age 40) and at risk for having affected children. Men who are premutation carriers are at risk for adult-onset FXTAS and will pass the premutation allele on to their female offspring. Males with greater than 200 repeats are at significant risk for intellectual disability and behavior problems, and females with more than 200 repeats also have some risk for intellectual disability and learning problems, but decreased risk compared to males with more than 200 repeats.

Mutations with greater than 200 repeats are termed *full mutations*.

### Epidemiology

The estimated prevalence of individuals with full mutations is 1 in 3,700 white males and 1 in 2,500 black males. However, a recent newborn incidence study for full mutation (>200 repeats) in males found the incidence to be 1 in 5,164 (ethnicity unknown). The prevalence of fragile X-affected heterozygous females is estimated to be 1 in 7,000. Prevalence for unaffected female premutation carriers is as high as 1 in 259.

### Etiology

As described earlier, fragile X syndrome is a disorder of trinucleotide repeat expansion. The gene for fragile X is located at the end of the long arm of the X chromosome (band Xq27.3). This X-linked condition is caused by an abnormal expansion of trinucleotide repeats (>200, which leads to excess methylation of the gene and subsequent gene silencing) and rarely by a direct mutation in the gene sequence. Either of these loss-of-function mutations in the *FMR1* gene leads to inadequate production of FMRP for those with a full mutation. FMRP is an RNA-binding protein. Its action through inhibition of dendritic protein synthesis modulates dendritic maturation and accompanying synaptic plasticity. The metabolic pathway affected (metabotropic glutamate receptor [mGluR]-mediated translation) is being targeted for potential therapeutic intervention with experimental trials underway.

Premutation carriers who are less affected in terms of cognitive delays are presumed to be influenced by a less than full reduction in the amount of FMRP than is seen in individuals with a full mutation. Affected individuals with premutations are also affected by an additional pathogenetic mechanism. Premutation individuals make an excess of messenger RNA (mRNA) transcript of the *FMR1* gene, although this mRNA increase does not lead to an increase in FMRP. An excess of mRNA transcript is not seen in full mutations because the gene is effectively silenced. The increased levels of mRNA seem to have a toxic effect on cell signaling. POI and FXTAS are associated with increased levels of *FMR1* gene mRNA transcript. The ovarian dysfunction in POI and the adult-onset neurologic abnormalities in FXTAS are tentatively causally linked to mRNA cellular toxicity.

### Risk Factors

Fragile X syndrome has no known ethnic or socioeconomic predilection. There are no known risk factors. Any individual, male or female, with an unknown cause for developmental delay should be strongly considered for evaluation.

## DIAGNOSIS

### Signs and Symptoms

Early recognition of the fragile X syndrome in childhood is very difficult; therefore, pediatricians and other physicians should have a high index of suspicion. Delayed diagnosis is a significant problem in early childhood. Delayed attainment of motor milestones,

hypotonia, developmental delay (especially speech), and unusual behaviors are the predominant features seen in early childhood. Feeding problems and gastroesophageal reflux are common. The characteristic physical signs in adults (large head, long face, prominent forehead, chin, and ears; joint laxity; macro-orchidism) usually do not develop until the postpubertal period. (See Figure 253-1, Figure 253-2, Figure 253-3, Figure 253-4, Figure 253-5, Figure 253-6, and Figure 253-7.)

Behavior issues in early childhood include features consistent with attention-deficit/hyperactivity disorder, obsessive or perseverative activity, emotional lability, or hypersensitivity to stimuli. Autism spectrum disorders and psychiatric comorbidities occur frequently.

Other potential abnormalities are seen in these additional areas—ophthalmologic (strabismus), orthopedic (joint laxity), cardiac (mitral valve prolapse), skin (excessive softness and smoothness), and neurologic (seizures). Neuroradiologic abnormalities have been reported.

Affected males typically have moderate intellectual disability, and affected females have mild intellectual disability.

**Figure 253-1** Patient 1 with Fragile X syndrome at 2 years of age, manifesting some of the physical signs (blue eyes, long face, prominent forehead) seen in Fragile X. The other features like large ears and prominent jaw are more obvious at ages 7 and 25, as is characteristic of Fragile X syndrome. See Figures 252-2 and 252-3.

### Differential Diagnosis

Other conditions to be considered in the differential diagnosis are Sotos syndrome (similar craniofacial features, overgrowth, and learning disability), Prader-Willi syndrome (a subset of fragile X patients can manifest hyperphagia, as seen in Prader-Willi syndrome, in addition to early hypotonia and developmental delay), autism spectrum disorders, and attention-deficit/hyperactivity disorder.

### Diagnostic Approach

Any child with delayed motor milestones, developmental delay (especially speech), intellectual disability, and autistic-like and other behaviors should be

**Figure 253-2** Patient 1 at 7 years of age.

**Figure 253-3** Patient 1 at 25 years of age.

considered for molecular testing, regardless of a negative family history. (See Figure 253-8.) A positive family history for intellectual disability (especially but not exclusively in males) is another strong indicator for testing. Concurrent microarray comparative genomic hybridization (CGH) is recommended to examine for non-fragile X conditions.

Adults in the family with signs or symptoms of primary ovarian insufficiency (onset of menopause prior to age 40 years) or tremor and/or ataxia (as seen in FXTAS) should be referred for testing.

### Laboratory Findings

Molecular fragile X testing typically analyzes the number of trinucleotide repeats in conjunction with Southern blot analysis and polymerase chain reaction. Newer techniques are being developed that overcome some current limitations in testing.

The laboratory testing was discussed earlier in the definition of fragile X syndrome. In brief, 5 to

44 repeats is a normal value; 45 to 54 repeats is an intermediate result usually without significance; 55 to 200 repeats is seen in premutation carriers; greater than 200 repeats is found in affected individuals. Females will have 2 alleles to be measured and males only 1 allele.

**Figure 253-4** Patient 2 with Fragile X syndrome at 1 year of age, with blue eyes and frontal bossing. Figures 253-5 through 253-7 demonstrate the progression of craniofacial features (long face, prominent forehead, and prominent jaw). Oftentimes the craniofacial features do not become obvious until after the onset of puberty.

**Figure 253-5** Patient 2 at 3 years of age.

**Figure 253-6** Patient 2 at 13 years of age.

**Figure 253-7** Patient 2 at 16 years of age.

### Imaging

Although neuroradiologic abnormalities (decreased cerebellar volume, increased ventricular volume, and increased white matter hyperdensity) have been reported in fragile X syndrome, routine neuroradiologic studies are not recommended. They should be performed as clinically indicated.

### Diagnostic Procedures

No additional diagnostic procedures other than those discussed earlier are necessary. Developmental and behavioral assessments will assist in the supportive and therapeutic management of affected individuals.

### Classification

Fragile X syndrome is the most common type of heritable intellectual disability. It is an X-linked semi-dominant condition with variable manifestation in males and females and has varied potential adult manifestations. It is one of the *FMR1*-related disorders that include fragile X syndrome, FXTAS, and *FMR1*-related POI.

## MANAGEMENT

### Treatment Approach

Currently, no specific treatment is available. Exciting advances are expected to make significant contributions to treatment based on the neurobiology of fragile X syndrome. Educational and behavioral interventions (occupational therapy, physical therapy, speech therapy, anticipatory management, and special education) are indicated for affected individuals. Pharmacologic therapy should be individualized, used to treat psychiatric presentations, and considered an adjunct for treatment of variable behavioral challenges not responding to environmental and behavioral interventions. An integrated behavioral and pharmacologic

program under the guidance of an experienced developmental team may prove helpful. Standard medical care is recommended for any health-related problem.

Because the fragile X syndrome is a genetic condition, close attention should be paid to a thorough examination of the family history and to the possibility of recurrence within the family. Genetic counseling to review recurrence risks and potential testing would be helpful. Premutation carrier females are at risk for having affected males and females because of the expansion of the trinucleotide repeats in female meiosis. The recurrence risk counseling is sufficiently complicated that referral to a medical geneticist or genetic counselor is indicated.

### Specific Treatments

Targeted treatments are under development.

## ONGOING CARE

### Follow-up

Appropriate behavioral, pharmacologic, and special education interventions should occur as indicated by the individual circumstances. Ongoing discussions about recurrence risk for subsequent offspring can be helpful to the family. Adults in the family should be aware of associated risks.

### Complications

Medical issues should be treated by standard interventions. Intellectual disability and behavioral problems are the predominant complications that need appropriate supportive and pharmacologic treatments. Family members should be counseled about possible primary ovarian insufficiency (onset of menopause prior to age 40 years) or FXTAS (tremors or ataxia after age 50 years).

### Prognosis

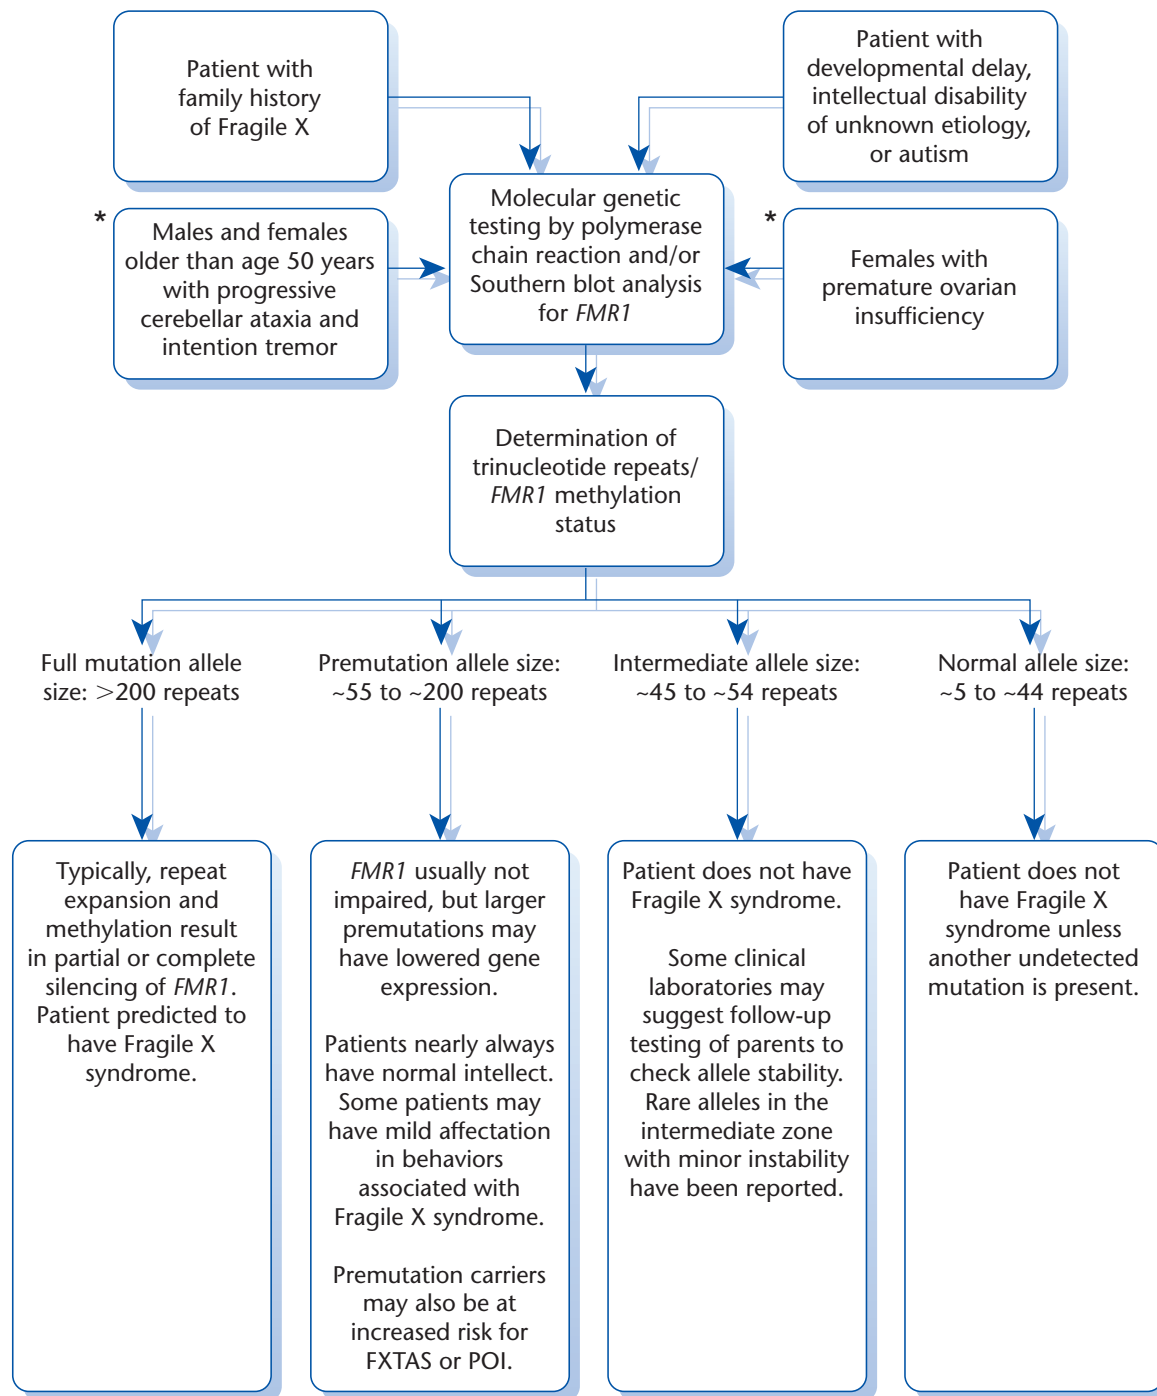

Children with fragile X syndrome will need significant educational and behavioral assistance. They will typically require custodial care as they make the transition to adulthood. Fragile X syndrome is one of the *FMR1*-related disorders, and assessment of additional family members should be considered because the additional risks will affect the longitudinal care of the patient and family.

### Prevention

Prenatal diagnosis is available for families that desire such testing. Population-wide neonatal screening is being investigated but is not currently available.

## WHEN TO REFER

- Delayed motor milestones
- Developmental delay, especially speech
- Abnormal behavior (nonisolated attention deficit/hyperactivity disorder or autistic features)
- Typical physical features (craniofacial abnormalities [long face; prominent forehead, chin, and ears] and macro-orchidism)

**Figure 253-8** Testing algorithm for *FMR1*-related disorders. The boxes identified with asterisks (\*) identify individuals to be considered for *FMR1* molecular testing. (From Saul RA, Tarleton JC. *FMR1*-related disorders. In: GeneReviews. Pagon RA, Adam MP, Ardinger HH, et al, eds. Copyright © 1993-2015, University of Washington, Seattle. All rights reserved. Available at: [www.ncbi.nlm.nih.gov/books/NBK1384](http://www.ncbi.nlm.nih.gov/books/NBK1384). Updated April 26, 2012.)

FXTAS, Fragile X-associated tremor/ataxia syndrome; POI, primary ovarian insufficiency

- Positive family history for intellectual disability, females with primary ovarian insufficiency (menopause prior to age 40 years), or males with adult-onset tremor or ataxia

### WHEN TO ADMIT

There are no unique situations pertinent to fragile X syndrome.

### Chapter 254

## FUNGAL INFECTIONS (SYSTEMIC)

Kenneth A. Alexander, MD, PhD; Adriana Cadilla, MD; Nadia K. Qureshi, MD

A systemic fungal infection in pediatrics is not a common occurrence. Nevertheless, in recent decades, the incidence of invasive fungal infections and the need to recognize and appropriately manage them in pediatrics have increased. More than 100,000 species of fungi have been identified, of which only a few are known to be pathogenic. This chapter includes the common systemic fungal infections seen in pediatrics. Though experts differ in their opinions regarding taxonomy and classification of fungi, in general, systemic mycoses are divided into 2 categories based on their pathogenicity:

- Primary systemic mycoses, such as histoplasmosis, coccidioidomycosis, and blastomycosis, which can infect immune-competent individuals.
- Opportunistic mycoses, such as invasive candidiasis, aspergillosis, cryptococcosis, and mucormycosis, which mainly infect immunocompromised individuals.

### ASPERGILLUS

#### Etiology

*Aspergillus* exists as a hyaline mold with septated hyphae that typically branch at acute angles. *Aspergillus* most commonly reproduces asexually, forming conidia, the infectious form of the mold (Figure 254-1 and Figure 254-2). There are more than 180 known species of *Aspergillus*, and an increasing number of *Aspergillus* species are being described as human pathogens. The species most commonly isolated in human disease is *A fumigatus*, which, on culture, appears as gray-green colonies. Other common human pathogens include the toxin-producing species, *A flavus* (colonies are yellow-brown on the surface and gold colored or red-brown underneath), an amphotericin B-resistant species, *A terreus* (colonies are beige to cinnamon-colored on the surface and white-brown underneath), *A niger* (colonies are black on the surface and white-yellow underneath), and *A nidulans* (colonies are green-yellow on the surface and purple-red or red-brown underneath).

#### Epidemiology

*Aspergillus* species are ubiquitous in nature, and are present in soil, decaying vegetation, and air and water supplies. Humans acquire *Aspergillus* through the

**Figure 254-1** Conidia and phialoconidia of *Aspergillus fumigatus*. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

**Figure 254-2** This micrograph depicts the histologic features of aspergillosis, including the presence of conidial heads. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

constant inhalation of aerosolized conidia. As the conidia enter the lung, macrophages clear them, usually with little local inflammatory response. Occasionally, the conidia will germinate into the tissue-invasive hyphae form. These hyphae can invade the tissue and trigger a series of host-immune responses. In all cases of invasive aspergillosis, angioinvasion by *Aspergillus* hyphae, with resultant tissue hypoxia and necrosis, is an important factor in disease pathogenesis.

Fortunately, invasive aspergillosis is rare, yet it remains a common cause of morbidity and mortality in immunocompromised patients. The incidence of invasive disease depends on many factors, and varies between 0.1% and 11% among the various at-risk populations studied. Generally speaking, the incidence of invasive aspergillosis is highest among allogeneic hematopoietic stem cell transplant (HSCT) recipients (human leukocyte antigen [HLA]-mismatched individuals are at a higher risk than HLA-matched individuals),

followed by lung transplant recipients. Autologous HSCT and liver and kidney transplant recipients generally have lower incidence of invasive aspergillosis.

Just as the incidence of invasive aspergillosis varies among at-risk groups, so too does *Aspergillus*-related mortality. A systematic review by Lin and colleagues in 2001 showed that the crude fatality rate (CFR) of invasive aspergillosis was 58%. When stratified by underlying comorbidities, the CFR of HSCT was 86.7%, the highest of any group. Patients with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) had the next highest CFR, 85.7%; those with liver transplants had a CFR of 67.6%; and those with kidney transplants had a rate of 62.5%. Patients with leukemia and lymphoma along with lung and/or heart transplantation had the lowest CFR (49.3% and 31%, respectively). The lower incidence of mortality secondary to invasive aspergillosis among patients with lung transplants is likely because of the widespread post-transplantation use of prophylactic aerosolized antifungal agents. Allogeneic HSCT recipients with invasive aspergillosis generally face higher mortality rates than do autologous transplant recipients. Furthermore, mortality among patients with invasive aspergillosis and relapsed leukemia approaches 100%. Cerebral aspergillosis, which carries a mortality rate of more than 90%, is especially problematic. The incidence of cerebral aspergillosis is not well established; studies suggest that cerebral aspergillosis may be present in 30% to 39% of patients diagnosed with invasive aspergillosis at other sites.

In immunocompetent patients, invasive forms of aspergillosis occur rarely, typically after exposure to *Aspergillus* conidia. Infections in such patients include pulmonary aspergillosis, *Aspergillus* tracheobronchitis, sinusitis, and very rarely, disseminated disease. In patients predisposed to sinusitis and chronic lung disease, aspergillomas may form in the sinuses and in devitalized areas of the lungs.

A few diseases are attributable to noninvasive *Aspergillus* infections, most resulting from an exuberant immune response to the colonizing *Aspergillus*.

### Risk Factors

As with most fungal infections, host risk factors are related to underlying disease; few immunocompetent hosts develop invasive aspergillosis. Risk factors can be divided by level of associated risk. High-risk patients are those undergoing long-term immunosuppressive therapy (corticosteroids or immunomodulating agents), such as HSCT recipients with graft-vs-host disease, and solid organ transplant recipients with acute or chronic graft rejection. Also at high risk are patients with hematologic malignancies (particularly acute myelogenous leukemia, especially relapsed), and patients with prolonged and severe neutropenia. Intermediate-risk patients are those who have received autologous HSCTs and solid organ transplant recipients. Low-risk patients include those with severe malnourishment, multiple myeloma, long-term corticosteroid treatment, HIV/AIDS, diabetes, and obstructive pulmonary disease. Recently, select patients in intensive care units (ICUs; without malignancy) have been described as having an increased risk of invasive

aspergillosis. Patients with chronic granulomatous disease (CGD) have an elevated risk for invasive pulmonary aspergillosis, which typically presents insidiously within the first 20 years of life.

## Diagnosis

### Signs and Symptoms

The symptoms of invasive aspergillosis depend on the site of the disease.

**PULMONARY ASPERGILLOSIS.** Patients with invasive pulmonary aspergillosis typically present with fever, cough, dyspnea, and pleuritic chest pain. A pleural effusion and pneumothorax may be present, and if angioinvasion has occurred, hemoptysis may ensue. It should be noted that the presentation of pulmonary aspergillosis in children with CGD can be insidious, marked by vague complaints, fever, and an elevated erythrocyte sedimentation rate.

**ASPERGILLUS TRACHEOBRONCHITIS.** Patients with *Aspergillus* tracheobronchitis typically present with dyspnea, cough, chest pain, and fever. Hemoptysis and wheezing are sometimes present, and most patients have a demonstrable decrease in their measured pulmonary function. *Aspergillus* tracheobronchitis can present in 3 ways: obstructive tracheobronchitis (common in patients with AIDS and heart transplants), characterized by noninflammatory mucus obstruction; pseudomembranous tracheobronchitis (common in lung transplant recipients), characterized by extensive inflammation and a membranous cover of the respiratory mucosa; and ulcerative tracheobronchitis (seen primarily among lung transplant recipients), in which the infection occurs at the tracheal suture line between the graft and the host.

**ASPERGILLUS SINUSITIS.** Sinus disease typically presents with headache, fever, epistaxis, and ear or nasal discharge. Also commonly noted is localized pallor of nasal septum or mucosa. With disease advancement, proptosis and cranial nerve palsies can occur. Although *Aspergillus* sinusitis can lead to invasion of bone and deep soft tissues, these are late findings that are associated with high morbidity and mortality. It is important to note the similarity of *Aspergillus* sinus disease with mucormycosis sinus disease because antifungal therapies for these 2 entities differ.

**CEREBRAL ASPERGILLOSIS.** The cerebral form of invasive aspergillosis can be seen in up to 30% of patients with invasive aspergillosis and typically presents with focal neurologic symptoms, altered mental status, hemiparesis, and cranial nerve palsies. Headache, nausea, and vomiting are present less frequently. *Aspergillus* is the most common cause of cerebral abscesses in patients with HSCT, usually resulting from dissemination of pulmonary infection.

**DISSEMINATED ASPERGILLOSIS.** Disseminated aspergillosis is typically an extension (or progression) of pulmonary disease, and occurs in patients who have experienced a long period of immunosuppression. Patients with disseminated aspergillosis present with a combination of symptoms based on the location of the primary focus and disseminated sites.

**OTHER.** Osteomyelitis, septic arthritis, and cardiac as well as ocular infections are rare forms of invasive aspergillosis. Cardiac involvement may present as

endocarditis, pericarditis, or myocarditis. The presentation is clinically indistinguishable from cardiac disease because of other infectious causes. *Aspergillus* osteomyelitis presents similarly to bacterial osteomyelitis, with nonspecific symptoms, including fever and pain. The vertebral bodies and intervertebral disks are usually affected. Septic arthritis presents similarly to bacterial joint infections, with fever, joint pain, warmth, and erythema. Endophthalmitis may develop after *Aspergillus* keratitis infection or from hematogenous dissemination. Rarely, direct inoculation and surgical contamination have been implicated. This is a medical emergency because irreparable vision loss with destruction of the eye may occur. However, it is clinically indistinguishable from other infectious causes.

**NONINVASIVE.** *Aspergillus* species can cause several noninvasive forms of disease. Allergic bronchopulmonary aspergillosis, a form of steroid-dependent asthma, is characterized by elevated *Aspergillus* immunoglobulin (Ig) E, and occurs most commonly in patients with cystic fibrosis and asthma. Another form of noninvasive aspergillosis is allergic rhinitis/sinusitis. This is a localized infection, typically recurrent, in which patients present with hypertrophic sinus disease and nasal polyps. Lastly, aspergillomas (mycelial balls), a form of noninvasive disease, can also occur. In aspergillomas, *Aspergillus* grows in devitalized parts of the lung. Patients are typically symptom free, or may present with often life-threatening hemoptysis.

### Differential Diagnosis

The diagnosis of *Aspergillus* infections is challenging. Clinical symptoms early in the course of the disease are typically indistinguishable from infections caused by other pathogens. Advanced infections caused by *Aspergillus* are often easier to diagnose, but carry substantially higher rates of mortality and morbidity. Immunocompromised children must receive thorough evaluations, and special thought should be given to invasive *Aspergillus* infections. A high index of suspicion in the right setting (immunocompromised host at high risk) is required.

### Laboratory Findings

Early diagnosis of invasive aspergillosis is paramount because survival is related to early treatment. However, diagnosis remains difficult, as with many fungal diseases. *Aspergillus* is infrequently found on culture of bronchoalveolar lavage (BAL) specimens, and even very rarely on blood culture. Cultures of biopsy site specimens are also rarely diagnostic, and biopsy is often too risky, because patients with invasive aspergillosis tend to have other comorbidities (eg, thrombocytopenia). Accurate diagnosis of *Aspergillus* infection is also made challenging by the ubiquity of *Aspergillus* in the environment and the resultant frequent colonization of mucosal surfaces. This is strikingly important in the diagnosis of invasive sinus disease. Given the frequent colonization of mucosal surfaces, physicians must attempt to distinguish intercurrent *Aspergillus* colonization from invasive disease. For definitive diagnosis of *Aspergillus* sinusitis, pathologic evidence of tissue invasion is needed.

With the poor sensitivity of culture, several nonculture methods for the diagnosis of invasive aspergillosis have been established. A serum galactomannan (a polysaccharide component of the *Aspergillus* cell wall) assay has been developed for clinical use. The sensitivity and specificity of this assay have been studied and vary according to patient characteristics, definition of disease (proven, probable, or possible), and assay cutoff values. The reported sensitivity of the serum galactomannan assay for the diagnosis of invasive aspergillosis ranges from 16.4% to 100%; specificity is approximately 80%. The sensitivity of galactomannan in BAL fluid tends to be higher. Galactomannan levels can also be measured in cerebrospinal fluid (CSF) for the diagnosis of *Aspergillus* infection in the central nervous system (CNS), but their sensitivity and specificity are unknown. Only serum and BAL testing is currently approved by the US Food and Drug Administration (FDA). It is important to note that galactomannan assay results can be false-positive in samples from patients exposed to certain antimicrobials (eg, amoxicillin/clavulanate), from neonates colonized with *Bifidobacterium*, and rarely, from patients with other mycoses (eg, *Fusarium*, *Penicillium*, *Cryptococcus*, *Histoplasma*, *Blastomyces*). Despite some earlier reports, false-positive values are similar in children and adults.

Another nonculture diagnostic tool is a serum assay to detect (1,3)- $\beta$ -D-glucan (BDG; a fungal cell wall component). Again, sensitivity and specificity of the assay will vary according to patient characteristics, definition of disease (proven, probable, or possible), and assay cutoff values. This assay has a combined sensitivity of 55% to 100% and specificity of 87% to 93% for diagnosing invasive fungal disease in serum specimens; however, fungal expression of BDG is not limited to *Aspergillus*. Other fungi, including *Candida*, *Fusarium*, *Histoplasma capsulatum*, *Trichosporon*, *Saccharomyces cerevisiae*, *Sporothrix schenckii*, and *Acremonium* express BDG. In addition, BDG is a cell wall component of *Pneumocystis jiroveci*. As a consequence, BDG positivity in a sample is not specific for *Aspergillus*. Furthermore, as with the galactomannan assay, false-positive results can occur in patients receiving certain antibiotics (eg, cephalosporins, carbapenems, ampicillin/sulbactam) and in patients receiving intravenous immunoglobulins. False-positive BDG assay results can also occur with exposure to tubes and/or gauze containing cellulose membranes. Cerebrospinal fluid and BAL fluids may be tested as well, though sensitivities and specificities are unknown, and these are not FDA approved.

Polymerase chain reaction (PCR) assays have been developed to detect *Aspergillus*. A number of these assays are commercially available, but the lack of standardization makes them difficult to interpret. An evaluation of various commercially available methods found good overall results, with a sensitivity and specificity of 86.1% and 93.6%, respectively. Further research is needed before these methods become standard diagnostic tools that are universally recommended.

Other nonculture molecular methods for the diagnosis of invasive aspergillosis disease include in situ hybridization for detection of *Aspergillus* in histopathologic

specimens and a lateral flow device, a new device. The lateral flow device serves as point-of-care testing to detect *Aspergillus* antigen by a monoclonal antibody in BAL fluid and serum samples, with results analyzed in a short time. Preliminary studies are promising, but further research is needed.

When culture is available, it is important to verify the minimum inhibitory concentration of the drug, because of the emergence of triazole-resistant *A fumigatus* in certain parts of the world (particularly Europe). The predominant mechanism of resistance for these isolates is a mutation in TR<sub>34</sub>/L98H, which confers cross-resistance to the drug class. To date, very few azole-resistant isolates have been seen in the United States. A study that evaluated clinical *A fumigatus* isolates collected between 2011 and 2013 from different parts of the United States revealed a 5% incidence of *A fumigatus* isolates with a minimum inhibitory concentration greater than 1  $\mu$ g/mL to itraconazole, but none harbored the TR<sub>34</sub>/L98H mutation.

### Imaging

For sinus disease caused by *Aspergillus*, computed tomography (CT) frequently shows air-fluid levels, mucosal thickening, and with invasive disease, erosion of bony structures. In pulmonary infection in immunocompromised hosts, high-resolution CT will typically show ground glass attenuation surrounding a pulmonary nodule ("halo" sign). Following initial lesions, air crescents and cavitations may develop, usually as neutropenia resolves. Other characteristics of pulmonary aspergillosis seen on CT include enlarged lymph nodes, lobar infiltrates, and ground glass appearance of pulmonary parenchyma. Importantly, abnormal lung radiographic findings may not be as prevalent in younger children with pulmonary aspergillosis compared with the prevalence of abnormal findings in older children and adults. It should also be noted that, after the initiation of appropriate antifungal therapy, *Aspergillus* lesions will appear to worsen on imaging. This radiographic worsening is not itself indicative of treatment failure.

Patients with CGD who develop pulmonary aspergillosis often lack the lesions that are characteristically seen on radiologic imaging in other patients. Also, in some patients with CGD, aspergillosis evolves to a chronic, local progressive infection, most often involving the vertebrae, pleura, and chest wall.

In cerebral aspergillosis, CT scans may show 1 or multiple hypodense, well-demarcated lesions. These are sometimes noted as ring-enhancing lesions with surrounding edema, with or without associated hemorrhage, similar to other types of cerebral infections (Figure 254-3). Magnetic resonance imaging (MRI) may show an increased number of lesions with irregular ring enhancement, typically earlier in the disease process compared with CT scan.

Bone invasion by *Aspergillus* can be detected on plain film radiography, CT scan, and MRI. Bone involvement is seen most frequently in immunocompromised patients with advanced *Aspergillus* sinus disease, and in the chest wall and vertebra in patients with CGD. Radiographic findings of bone erosion caused by *Aspergillus* infection are similar to the

**Figure 254-3** Aspergillomas in a 10-year-old with Hodgkin lymphoma. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

radiographic findings of bone erosion caused by other fungi or bacteria.

## Management

### Treatment Approach

Effective treatment of *Aspergillus* infections requires early diagnosis and aggressive treatment. Delayed therapy is associated with increased mortality. Thus, any symptomatic child with high or intermediate risk of invasive aspergillosis merits prompt evaluation and serious consideration for empirical therapy. Whenever possible, immunosuppression should be reduced.

The following recommendations are extracted from the *Clinical Practice Guidelines for the Treatment of Aspergillosis*, published by the Infectious Disease Society of America (IDSA).

### Specific Therapy

First-line therapy for any invasive *Aspergillus* infection is voriconazole. Voriconazole is a cytochrome P450 inhibitor; therefore, significant drug-drug interactions may occur. Voriconazole is typically well tolerated, and the most common side effects include visual disturbances and hallucinations. Caution must be taken when the intravenous formulation is used because it uses a cyclodextrin carrier (renally cleared), which may accumulate in patients with renal insufficiency. Also, voriconazole exhibits a high degree of interpatient pharmacokinetic variability, so drug levels should be monitored to ensure adequate drug exposure while preventing toxicity. Drug concentration after 1 week of exposure should be 1 to 5.5 mg/L (ideally >2 mg/L). Liposomal formulations of amphotericin B are an alternative to voriconazole as primary therapy. It must be emphasized that reduction of immunosuppression is paramount in the treatment of invasive aspergillosis.

Amphotericin B, itraconazole, posaconazole, and the echinocandins (capsfungin and micafungin) are reserved for disease that does not respond to voriconazole, and for those unable to tolerate voriconazole therapy. If itraconazole is used, drug levels should be

obtained to ensure a therapeutic range is obtained (because of the drug's erratic bioavailability). Posaconazole oral suspension exhibits erratic absorption, but the delayed-release tablet and intravenous formulation deliver reliable serum drug levels. When the oral suspension is used, therapeutic drug monitoring may be necessary, although clear values have not yet been defined. Currently, data on a recommendation of combination therapy as the first-line approach are insufficient. For salvage therapy, a combination of antifungals with differing mechanisms of action may prove useful. Another option is to switch the antifungal for one with a different mechanism of action.

Special caution must be taken when choosing an antifungal agent for sinus disease, because voriconazole does not offer coverage for disease caused by *Zygomycetes* glomeromycetes (eg, mucormycosis), another common fungal sinus infection in immunocompromised patients. When there is a high suspicion for *Zygomycetes* mucormycosis, or if it cannot be ruled out, amphotericin B is the drug of choice.

Optimal duration of therapy for invasive aspergillosis has not been determined. Most experts advocate treatment for months, and often until the patient is capable of mounting a sufficient immune response. In fact, when a child recovers from invasive aspergillosis, should she/he become immunosuppressed again, antifungal treatment is recommended for prevention of recurrent infection.

Surgical resection of affected tissues is often required as adjunct therapy, especially in select cases of hemoptysis, pericardial disease, empyema, endocarditis, osteomyelitis, sinusitis, and cerebral lesions.

Despite the limited data supporting their use, granulocyte colony-stimulating factors may be given to children with aspergillosis and neutropenia.

### When to Admit

Children with suspected *Aspergillus* infection should be admitted until an accurate diagnosis is made and response to therapy has been demonstrated.

### When to Refer

The care of children with invasive *Aspergillus* infections requires consultation with an infectious disease specialist. For children with suspected sinus disease caused by *Aspergillus*, consultation with an otolaryngologist is also recommended. When the eye is involved, an ophthalmologist should be promptly consulted. In cases in which a biopsy or resection is sought, a surgeon specialist should be consulted.

### Ongoing Care

#### Follow-Up

For patients demonstrating adequate response, voriconazole is available as an oral formulation with excellent bioavailability. Drug levels should be monitored to ensure therapeutic levels are maintained. Patients with poor response will require prolonged hospitalization and investigation.

### Complications

In patients whose immune systems cannot be reconstituted or whose immune suppression cannot be decreased, invasive *Aspergillus* infections are frequently

fatal. Side effects of azole antifungal agents are uncommon. Voriconazole side effects include transient visual disturbances, hepatotoxicity, rash, and visual hallucinations. It should be noted that voriconazole and posaconazole are cytochrome p450 inhibitors. As such, the pharmacokinetics of many medications, including those commonly used after organ and stem cell transplantation, are altered with voriconazole and posaconazole therapy.

### Prognosis

In recipients of HSCT and lung transplantations, the use of prophylactic antifungal agents has dramatically reduced the incidence of invasive aspergillosis. Unfortunately, once invasive aspergillosis occurs, prognosis remains poor. The mortality of invasive aspergillosis in patients with HSCT remains high (55%–80%).

### Prevention

Prophylaxis against invasive aspergillosis is recommended in 3 specific situations: HSCT patients with graft-vs-host disease who are receiving immunosuppressive agents, neutropenic patients with acute myelogenous leukemia, and neutropenic patients with myelodysplastic syndromes. Also, close monitoring of high-risk patients is paramount, because a high index of suspicion is needed for the early detection and treatment of invasive aspergillosis.

## CANDIDA

### Etiology

*Candida* are unicellular yeasts with thin, small cell walls. *Candida* species reproduce by budding. There are more than 150 *Candida* species, of which only a few are pathogenic in humans. *Candida albicans* is the most commonly recovered species causing human disease, followed by *C parapsilosis*, *C tropicalis*, *C glabrata*, and *C krusei*. *C dubliniensis* is similar to *C albicans*, and its importance in human disease was recognized only recently. *C guilliermondii*, *C pseudotropicalis*, *C lusitanae*, *C pelliculosa*, *C rugosa*, *C norvegensis*, and *C inconspicua* are rare causes of human disease.

### Epidemiology

*Candida* was first described as a pathogen in the 1840s when it was recognized as a cause of oral thrush. In recent decades, invasive *Candida* infections involving 1 or more organ systems have become increasingly common. *Candida* infections of the skin and mucus membranes (oropharynx, esophagus, vagina, skin) are regarded as noninvasive forms of disease.

*Candida* species account for the majority of invasive fungal infections in the developed world. In the United States, *Candida* species are the fourth most common cause of nosocomial bloodstream infections in adults, and are the third most common cause of nosocomial bloodstream infections in children. Beginning with the development of antimicrobials decades ago and the subsequent development of life-saving procedures, the increased incidence of invasive *Candida* infections parallels advancements in medical care. Stem cell and solid organ transplantation, the use of chemotherapy for treatment of malignancies, and the implantation of prosthetic devices are all associated with increased

risk of invasive *Candida* infection. Likewise, the increased use of both broad-spectrum antimicrobials and long-term indwelling catheters has contributed to the estimated 207% increase in invasive fungal infections between 1979 and 2000. Unfortunately, the treatment of fungal infections has lagged behind other medical advances, and the mortality of invasive candidiasis remains high.

*Candida* species are commonly found on the skin, gastrointestinal tract, sputum, and female genital tract. The presence of colonizing *Candida* makes it difficult to interpret cultures obtained from these sites. Isolation of *Candida* from a normally sterile site is indicative of a true infection and requires prompt initiation of therapy and further investigation. In particular, it should be noted that blood cultures are rarely contaminated with *Candida*; a blood culture growing *Candida* should be considered diagnostic of invasive *Candida* infection.

### Risk Factors

The most commonly cited factors associated with invasive *Candida* infections include admission to an ICU, use of broad-spectrum antimicrobials, presence of central venous catheters (CVC), use of parenteral nutrition, presence of prosthetic devices, solid organ and stem cell transplantation, surgery (particularly abdominal), severe burns, hemodialysis, use of immunosuppressive drugs (steroids, chemotherapy, immunomodulators), and colonization with *Candida*.

In infants, prematurity, intubation, and gastrointestinal disease have been identified as risk factors for invasive *Candida* infections. Notably, premature neonates with birth weights less than 1,000 g are at increased risk for invasive candidiasis. Interestingly, a study in 2010 that assessed risk factors and predictors of candidemia in a pediatric ICU found a 10.7% risk of developing invasive candidemia in children with an underlying malignancy who had a CVC and had received vancomycin therapy for more than 3 days. This risk increased to 46% when parenteral nutrition and antimicrobial therapy for more than 3 days with anaerobic coverage were also present.

Although *C albicans* remains the most common species causing human disease, non-*albicans* species are becoming increasingly common, often accounting for more than 50% of all isolated *Candida* (cumulatively). Non-*albicans* species are sometimes associated with specific patient factors. For example, *C krusei* infections are more common in patients with stem cell transplants, previous treatment with fluconazole, hematologic malignancy, and neutropenia. *C tropicalis* is more often isolated from neutropenic patients and those with leukemia. *C parapsilosis* is most often seen in neonates and those with CVCs. *C glabrata* is more often isolated from older adults, those previously treated with antifungals, and solid organ transplant recipients.

### Diagnosis

#### Signs and Symptoms

Invasive candidiasis affects various organs and therefore, can cause a wide array of symptoms.

**CANDIDEMIA.** The isolation of *Candida* on blood culture is associated with various symptoms ranging from asymptomatic CVC infection to fever and severe sepsis. Approximately 50% to 70% of candidemic patients will have at least 1 positive blood culture. After the onset of candidemia, multisystem organ failure may ensue quickly. Thus, a positive blood culture requires prompt evaluation and treatment. Candidemia in immunocompromised patients may present as persistent fever despite broad-spectrum antibacterial therapy. In the neonate, symptoms of candidemia are nonspecific and may include temperature instability, lethargy, abdominal distention, hyperglycemia, feeding intolerance, apnea, and persistent thrombocytopenia.

**ENDOCARDITIS.** Fungal endocarditis is rare (<5% of all cases of infective endocarditis), and *Candida* species account for just over half of these cases. *Candida* endocarditis usually presents insidiously: with fever, with or without a murmur, and with positive blood cultures. Echocardiographic lesions are generally larger in *Candida* endocarditis than in bacterial endocarditis.

**OCULAR INFECTIONS.** *Candida* can cause either endophthalmitis or chorioretinitis. Ocular disease is historically regarded as a rare consequence of untreated or inadequately treated candidemia, in which patients rarely develop disease if treated appropriately. As such, a careful retinal examination by an ophthalmologist is an important part of the evaluation of a child with candidemia, and is recommended by the IDSA. In 2011, a prospective study of the incidence and results of ocular lesions in blood culture-proven candidemia showed a 16% incidence of ocular involvement, with just 1.6% of patients exhibiting endophthalmitis.

**CENTRAL NERVOUS SYSTEM.** Invasive candidiasis of the CNS most commonly affects parenchymal tissues and the meninges, with occasional formation of microabscesses. CNS candidiasis is more common in extreme age groups (neonates and elderly) and is often a complication of a neurosurgical procedure. In neonates, the term *hematogenous Candida meningoencephalitis* (HCME) is used. HCME is present in approximately 15% of cases of neonatal candidemia. Long-term follow-up is essential after neonatal HCME, because neurocognitive deficits are common in this condition. The majority of CNS infections are caused by *C. albicans*.

**DISSEMINATED.** Acute disseminated candidiasis occurs most commonly in patients with neutropenia caused by a hematologic malignancy. These patients will have acutely ill presentations, with positive blood cultures and multiorgan involvement. Many will exhibit discrete skin lesions characteristic of small vessel vasculitis.

Chronic disseminated candidiasis is also known as *hepatosplenic candidiasis*. It occurs most often in the severely immunocompromised host with a hematologic malignancy (eg, leukemia). Hepatosplenic candidiasis often presents when neutrophil counts begin to rise after a period of chemotherapy-induced neutropenia. It is characterized by multiorgan lesions (primarily liver and spleen) and typically presents with fever, abdominal pain, hepatosplenomegaly, and an elevated serum alkaline phosphatase.

**OTHER.** Septic arthritis, tenosynovitis, osteomyelitis, urinary tract infections, and pneumonia are other manifestations of invasive candidiasis. Septic arthritis and tenosynovitis caused by *Candida* present similarly to bacterial joint infections: with fever, joint pain, warmth, and erythema. *Candida* osteomyelitis also presents similarly to bacterial osteomyelitis, with nonspecific symptoms including fever and pain. In adults with *Candida* osteomyelitis, disease occurs most commonly in the axial skeleton (vertebrae, rib, and sternum); in children, however, the long bones (femur and humerus) are most commonly affected.

Genitourinary candidiasis occurs most commonly as a consequence of urinary catheter use and resolves with removal of the catheter. However, in neonates and in neutropenic patients, candiduria should be assumed to be a manifestation of renal candidiasis, which typically occurs as a complication of candidemia (and as such, consideration should be given for an extensive workup including a liver/spleen/kidney ultrasound, cardiac echocardiogram, eye examination, and in young infants and symptomatic patients, a lumbar puncture with examination of CSF specimens). Patients with renal candidiasis may present with pyelonephritis, hypertension, rising serum creatinine levels, or ureteral obstruction. Mycetomas (or fungus balls) may be detected with imaging of the genitourinary tract. This complication is uncommon, yet occurs with a higher frequency among neonates with candiduria and/or candidemia.

*Candida* pneumonia is rare, and most often occurs in the setting of neutropenia. This form of invasive disease typically presents with fever and radiologic evidence of disease. Similar to its isolation from a urinary catheter, *Candida* species isolated from an endotracheal tube or tracheostomy site usually reflects colonization rather than infection.

### Differential Diagnosis

Infections caused by *Candida* are clinically indistinguishable from same-site infections caused by other pathogens. Laboratory studies must be undertaken to determine the causative organism.

### Laboratory Findings

For direct visualization, a wet mount is quickly diagnostic and will show hyphae, pseudohyphae, and budding yeast cells. Addition of potassium hydroxide (which clears epithelial cells) aids in the visualization of hyphae and pseudohyphae. Calcofluor white-stained smears are another way to visualize the fungi.

In invasive candidiasis, blood cultures are diagnostic in 50% to 80% of cases, with growth usually detected within 18 to 74 hours. In genitourinary tract candidiasis, urine specimens may show yeast sediment with growth of *Candida*, though interpretation requires caution because true infection must be distinguished from colonization. The presence of *Candida* in urine casts suggests renal tissue invasion.

In the diagnosis of *Candida* meningitis, the CSF may be normal or may demonstrate pleocytosis with a lymphocytic predominance. A wet mount or Gram stain is positive in approximately 40% of cases, and hypoglycorrhachia with an elevated protein count may be seen.

Direct tissue biopsy is often needed for the diagnosis of chronic disseminated candidiasis, because blood cultures are rarely positive. Similarly, *Candida* must be isolated from the synovial fluid for the diagnosis of septic arthritis and tenosynovitis. For osteomyelitis, biopsy of the affected area of the bone is often required because blood cultures are typically negative. Because *Candida* can colonize the respiratory tract, particularly in patients receiving broad-spectrum antibiotics, the accurate diagnosis of *Candida* pneumonia requires a lung biopsy. The biopsy must demonstrate direct invasion of the fungus into the lung parenchyma.

Several nonculture techniques have been developed for the diagnosis of fungal infections. An assay to detect and measure the titer of BDG, a component of the fungal cell wall, has been approved by the FDA. For detection of invasive candidiasis, this assay has a reported sensitivity greater than 65% and a specificity greater than 80%, depending on the study and the associated cutoff value. Expression of BDG is not limited to *Candida*; BDG is also present in *Aspergillus*, *Fusarium*, and *Trichosporon*. The BDG assay will also sometimes detect *Histoplasma*, *Sporothrix*, *Blastomyces*, and *Pneumocystis jiroveci*. False-positive results have been reported in patients receiving hemodialysis with cellulose membranes, in patients receiving intravenous immunoglobulins, and in patients receiving amoxicillin-clavulanic acid and other  $\beta$ -lactam antibiotics. A few bacteria, including *Alcaligenes faecalis*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa* also produce BDG and may cause false-positive test results. Notably, this assay has not been validated in children, though a number of studies and reports show promise.

A second nonculture technique developed for the diagnosis of invasive candidiasis is the mannan and antimannan antibody assay. This assay has demonstrated a sensitivity of 80% and a specificity of 85% in the diagnosis of invasive candidiasis, and its sensitivity can be increased by serial testing. Although not yet standardized and not widely available, PCR assays are also used sometimes. In-house methods have shown more than 85% sensitivity and specificity, but no external validation studies have been conducted. Oligonucleotide probes that detect target nucleic acid sequences are also being developed, with the advantage of batch testing, but these are not widely available.

Newer studies are showing that a combination of nonculture diagnostics (BDG, mannan/antimannan antibodies/PCR) may offer increased sensitivity and specificity, leading to a quicker diagnosis of invasive candidiasis and earlier treatment of disease.

Once *Candida* has been identified as the cause of an infection, species determination is important as a predictor of antifungal susceptibility. *C. albicans* and *C. dubliniensis* strains are most often susceptible to the triazoles, polyene, and echinocandin antifungals, *C. glabrata* has an increased incidence of fluconazole resistance, and *C. krusei* is intrinsically resistant to fluconazole. *C. parapsilosis* strains tend to have higher echinocandin minimum inhibitory concentrations (MICs) compared with other species (though clinical significance of this observation remains unclear). *C. lusitanae* strains are resistant to amphotericin B.

For rapid identification of *C. albicans* and *C. dubliniensis*, the germ-tube test is used. An inoculum is placed into serum and it is monitored for germ-tube (hyphae) formation (occurs in <90 minutes). Another way to distinguish *C. albicans* from other *Candida* species is by peptide nucleic acid fluorescent in situ hybridization; this method is quicker but more expensive. Also, special media (eg, chromogenic media, in which species grow with differing pigments) can be used to isolate and identify *Candida*. Older methods of species identification, such as the API20C and API32C, which use biochemical assays to generate fungal profiles unique to different species, continue to be commonly used in today's laboratories.

### Imaging

Children with persistent candidemia and those suspected to have disseminated disease should undergo ultrasound imaging of the liver, spleen, and kidneys to further assess for disease. Echocardiography should also be performed to assess for *Candida*-related valvar and intracardiac vegetations, for annular and intramural abscesses, and for potentially infected intra- and extracardiac thrombi. Lumbar puncture and CNS imaging should be considered for all infants, and for older children with symptoms referable to the CNS. For patients with suspected pulmonary candidiasis, a CT scan is recommended. Lastly, all patients with candidemia should have an ophthalmology evaluation to rule out ocular disease.

### Management

#### Treatment Approach

The isolation of *Candida* from any normally sterile site is diagnostic of infection. As such, antifungal therapy should be initiated immediately. Selection of an appropriate antifungal agent is based on several considerations: How old is the child? Was the child recently treated with a triazole antifungal? What are the child's comorbidities? How ill is the child? Is there suspicion for disseminated or CNS infection? Does the child have intravascular catheters or other implanted foreign bodies? What strains of *Candida* are isolated most commonly in the care environment? What are the susceptibilities of *Candida* species in the care environment?

The following recommendations are extracted from the *Clinical Practice Guidelines for the Management of Candidiasis: 2009*, published by the IDSA.

#### Specific Therapy

Candidemia in the non-neutropenic host may be treated with fluconazole provided there is no recent history of triazole use and no concern for CNS disease and *C. glabrata* or *C. krusei*. An echinocandin is preferred if the patient is moderately to severely ill or was recently treated with a triazole antifungal drug, or if a likely fluconazole-resistant isolate is found (*C. glabrata* and *C. krusei*). As an alternative, moderately to severely ill children may be treated with amphotericin B (lipid formulation [preferred because of its decreased toxicity] or deoxycholate). Voriconazole can be used as step-down therapy for children with *C. krusei* or those with voriconazole-susceptible *C. glabrata*. Because

voriconazole has high intra- and interpatient variability, therapeutic drug monitoring should be performed for all patients being treated with this drug. Patients should be treated for at least 14 days after the first negative culture. Early removal of any indwelling intravascular catheters is essential.

For candidemia in neutropenic children, first-line therapy options include an echinocandin or lipid formulation amphotericin B. Fluconazole may be used if the child has had no recent triazole exposure, is only mildly ill, and is unlikely to be infected with *C glabrata* or *C krusei*. Voriconazole may be used when infection with molds is also suspected. For treatment of *C glabrata*, an echinocandin should be used. When *C parapsilosis* is isolated, fluconazole or liposomal amphotericin B is the drug of choice. In cases of *C krusei*, an echinocandin, liposomal amphotericin B, or voriconazole should be used. Again, patients should be treated for at least 14 days after the first negative culture or for 14 days after resolution of neutropenia (whichever is longer). Early removal of any indwelling intravascular catheters is strongly recommended.

When treating a neonate with candidiasis, disseminated infection is assumed, and treatment with either amphotericin B deoxycholate (lipid formulation amphotericin can be used if genitourinary involvement is excluded) or fluconazole is recommended. Treatment duration is typically 3 weeks; CSF and ophthalmologic evaluation is strongly recommended. Removal of CVCs is strongly advised.

Treatment of *Candida* endocarditis entails a 2-step approach. During the 6- to 8-week period of induction therapy, lipid formulation amphotericin B with or without flucytosine is used. Alternatively, an echinocandin or amphotericin B deoxycholate may be given. Surgical removal of any sized vegetation as well as removal of potentially infected prosthetic material is strongly recommended. Following the course of induction therapy, a protracted course of triazole treatment is recommended. In patients who cannot undergo removal of an infected valve, lifelong suppression therapy with fluconazole is recommended. In neonates, medical treatment alone may suffice, with amphotericin B deoxycholate being the most commonly used drug.

Treatment of *Candida* endophthalmitis requires active consultation with an ophthalmologist. Mild disease may be treated with fluconazole; severe disease should be treated with amphotericin B deoxycholate and flucytosine. For patients intolerant of amphotericin B deoxycholate, lipid formulation amphotericin B, voriconazole, or an echinocandin may be used. Treatment should continue for at least 4 to 6 weeks until there is clinical evidence of disease resolution. Surgical intervention is recommended in severe disease.

For *Candida* infections of the CNS, first-line therapy includes lipid formulation amphotericin B, with or without flucytosine, for several weeks, followed by fluconazole once the patient is clinically stable and a response to therapy is seen. Alternatively, fluconazole monotherapy may be used in patients who do not tolerate lipid formulation amphotericin B. Treatment should continue until signs and symptoms of disease abate and CSF abnormalities have resolved. Although voriconazole achieves high CSF concentrations, no

reports of its use in CNS candidiasis have been published. As such, the use of voriconazole for treatment of CNS *Candida* infections cannot be recommended at this time. Posaconazole crosses the blood-brain barrier poorly, so it is not recommended for treatment of CNS infections.

*Candida* infections of the genitourinary tract require investigation before initiation of treatment. Asymptomatic urinary catheter-associated candiduria is treated with catheter removal; no additional therapy is needed in the normal host. *Candida* urinary tract infections in neutropenic patients, low-birth-weight infants, and symptomatic immunocompetent patients should be viewed as manifestations of systemic infections and are, therefore, treated according to the recommendations for treatment of systemic candidiasis (neutropenic, neonate, and immunocompetent). Cystitis and pyelonephritis should be treated with oral fluconazole for 2 weeks. When a fluconazole-resistant strain is isolated, conventional amphotericin B should be used with or without the addition of flucytosine (for select cases of cystitis, flucytosine may be used alone). For “fungal balls” in the renal pelvis or collecting system, amphotericin B deoxycholate with or without flucytosine should be used until symptoms resolve and cultures are negative. Fluconazole may be an effective option. In neonates with fungal balls, medical therapy alone is usually effective; in older individuals, surgery is strongly recommended. Alternatively, fluconazole may be used when *C glabrata* is not suspected. When treating urinary tract infections, it must be noted that fluconazole is the only triazole antifungal that is excreted predominantly in the urine.

*Candida* osteomyelitis should be treated with lipid formulation amphotericin B for 2 weeks, followed by a 6- to 12-month course of fluconazole. Alternatively, fluconazole may be used for the entire treatment period. Alternative regimens for treatment of *Candida* osteomyelitis also include the use of an echinocandin for 2 weeks, followed by fluconazole for 6 to 12 months. Surgical debridement may be beneficial in some cases. Septic arthritis should be treated with fluconazole for at least 6 weeks or with a combination of lipid formulation amphotericin B (or an echinocandin) for 2 weeks, followed by fluconazole to complete 6 weeks of therapy.

### When to Admit

Children with an invasive *Candida* infection should be admitted until clearance of candidiasis is demonstrated and clinical improvement noted.

### When to Refer

All invasive *Candida* infections require consultation with an infectious disease specialist.

### Ongoing Care

#### Follow-Up

Because neurocognitive deficits are common in neonates with disseminated *Candida* infection, neonates with invasive *Candida* infection will need long-term care, including enrollment into an early intervention program. Children with endocarditis, and those with prosthetic devices that cannot be removed, will need long-term, and possibly lifelong, suppressive antifungal

therapy. Those receiving long-term therapy will need monitoring for adherence and toxicity.

### Complications

As noted before, neonates with disseminated disease are at high risk for developmental delay, and are at increased risk for periventricular leukomalacia, chronic lung disease, and retinopathy of prematurity. Other complications may arise from invasive procedures performed to aid in diagnosis (eg, biopsy) or treatment (eg, vegetation removal, prosthetic device removal, fungal ball resection, medication side effects) of *Candida* disease. Some patients may experience recurrence of infection.

### Prognosis

With reports of mortality as high as 47% and surveys demonstrating 14.5% mortality in adults and 10% in children, prognosis of invasive *Candida* infection continues to be poor. Improved survival has been demonstrated with early treatment initiation (within 12 hours of illness onset). Therefore, a high index of suspicion is needed for invasive *Candida* infection, and should be followed by prompt initiation of antifungal therapy, especially in patients with multiple risk factors.

### Prevention

In neonatal ICUs, the rates of *Candida* infections among very low-birth-weight infants vary widely; anti-*Candida* prophylaxis with fluconazole should be considered for very low-birth-weight infants in units with high incidence of *Candida* infections. Similarly, fluconazole prophylaxis is recommended for high-risk adults in ICUs, particularly in those with high rates of candidiasis. High-risk solid organ transplant recipients (pancreas, small bowel, and high-risk liver transplants [defined as patients with at least 2 of the following risk factors: retransplantation, creatinine >2 mg/dL, choledochojejunostomy, intraoperative transfusion of >40 units of blood products, surgery duration >1 hour, or known *Candida* colonization]) should receive fluconazole or lipid formulation amphotericin for 7 to 14 days after transplantation. In special circumstances, patients with an expected prolonged period of chemotherapy-induced neutropenia may start treatment with fluconazole, posaconazole, or capsosungin during induction therapy and continue for the duration of the neutropenia. Lastly, stem cell transplant recipients with neutropenia should receive fluconazole, posaconazole, or micafungin for the duration of the neutropenic phase.

The physician must be reminded that an important risk factor for invasive *Candida* infection is the use of broad-spectrum antimicrobials. Judicious use of antimicrobial therapy is warranted not only to prevent the emergence of multidrug-resistant bacteria, but also to decrease the incidence of invasive candidiasis.

## CRYPTOCOCCUS

### Etiology

*Cryptococcus* is an encapsulated yeast that is able to reproduce either sexually (*Filobasidiella*) or asexually. More than 30 species have been described, but only 2 are well documented as pathogenic in humans. The most commonly reported species causing human disease is *C. neoformans* (~88.6%). *C. gattii* is the other

common species causing human disease (~11.4%). Mycology advancements led to the division of pathogenic *Cryptococcus* species into 5 serotypes (based on capsular polysaccharides) and 8 molecular types. *C. neoformans* is composed of 3 serotypes and 4 molecular types (*C. neoformans* variant *grubii* [serotype A, molecular type VNI and VNII], *C. neoformans* variant *neoformans* [serotype D, molecular type VNIV], and hybrid *C. neoformans* [serotype AD, molecular type VNIII]). *C. gattii* species is divided into 2 different serotypes and 4 molecular types (serotype B and C, molecular types VGI, VGII, VGIII, VGIV). On a molecular level, with limited data, *C. neoformans* variant *grubii* (serotype A, VNI) is the most commonly isolated species. *C. gattii* VGII deserves special mention because it was recognized as the most commonly isolated species during a 2004–2010 outbreak in North America.

### Epidemiology

*Cryptococcus* species is ubiquitous in nature; ecologic niches are species dependent. *C. neoformans* variant *grubii* (serotype A) and *C. neoformans* variant *neoformans* (serotype D) can be found in the droppings and nests of pigeons, and less frequently in droppings of turkeys, chickens, canaries, and parrots. Historically, *C. neoformans* variant *grubii* (serotype A) has been identified worldwide and *C. neoformans* variant *neoformans* (serotype D) has primarily been isolated in Europe. In contrast, *C. gattii* (serotypes B and C) was not isolated from pigeon droppings, but was most commonly associated with the *Eucalyptus* tree. Historically, it was present in tropical and subtropical areas. However, the emergence of *C. gattii* in Vancouver, British Columbia, Canada, and the Pacific northwest United States since 2001 has changed this association. *C. gattii* is now isolated in a different (temperate) climate, and from different types of trees (fir, maple, and oak trees), as well as freshwater, seawater, and soil.

The emergence of *C. gattii* in British Columbia and the Pacific northwest United States highlights an important change of the environmental niche of the organism, as well as a change in the type of host infected. *Cryptococcus* was recognized primarily as an opportunistic pathogen, that is, one that causes illness in a predisposed host. Historically, most illnesses caused by *Cryptococcus* were found among patients with HIV/AIDS and other severely compromised immune systems. Of the 218 cases reported between 1999 and 2007 in British Columbia, 62% had no immunocompromising condition, whereas only 3 cases occurred in children (2 used inhaled corticosteroids, 1 for a chronic respiratory disease and 1 for a genetic disorder). In contrast, of 60 cases of *C. gattii* infection reported in the United States between 2004 and 2010, 81% had an underlying immunocompromising condition (3 had HIV).

*Cryptococcus* has been widely studied, and a number of virulence factors have been identified. Factors that are recognized as most important include its capsule, its ability to produce melanin, and its thermotolerance. Foremost is the polysaccharide capsule, whose virulence is multifactorial. Its necessity was demonstrated in a study with loss of virulence by an acapsular strain, with its return as the capsule was

restored. The ability of *Cryptococcus* to form melanin is also believed to be an important virulence factor, but the exact mechanism is not well understood. An early animal study demonstrated lower virulence in strains lacking melanin compared with melanin-producing strains. The third important virulence factor is the ability of *Cryptococcus* at both environmental and higher temperatures (ie, 37°C). Growth at higher temperatures is essential for pathogenic microorganisms. Distinction among species is important: it has been noted that *C gattii* infections tend to produce cryptococcomas more often than *C neoformans*, and their presence will affect management.

Invasive infection is largely dependent on the status of the host's immune system and the virulence of the infecting strain. Infection begins with the inhalation of aerosolized organisms (believed to be in the form of either dehydrated yeast or basidiospores) into the alveoli, where alveolar macrophages kill the organism and recruit cytotoxic cells and chemokines. In the majority of hosts, the yeast is fully eliminated. Alternatively, proliferation of the yeast can occur, with or without dissemination of the organism to other sites. In some cases, a small dormant lung-node complex is formed, and the organisms may be reactivated after immunosuppression. Rarely, direct inoculation of the yeast leads to a localized skin infection.

Before the AIDS epidemic, cryptococcal disease was scantily described. With the emergence of AIDS, *Cryptococcus* became a frequently diagnosed opportunistic infection. In developed countries, the incidence of cryptococcal disease in patients with AIDS has decreased with the use of highly active antiretroviral therapy (HAART), but it continues to be a major burden in low-to-middle-income regions, particularly sub-Saharan Africa. In the United States, incidence of disease in patients without HIV infection is estimated at 0.2 to 0.9 in 100,000. A higher incidence is noted in patients with AIDS (2–7 in 1,000) but it is significantly decreased from the pre-HAART era (17–66 in 1,000). In comparison, incidence among patients with AIDS in sub-Saharan Africa is 14 in 1,000, even in the post-HAART era. Worldwide, in patients with HIV/AIDS, approximately 950,000 cases of cryptococcal meningitis are seen each year. Interestingly, cryptococcal disease has remained rare in children, even in children with HIV/AIDS, with an occurrence rate of less than 0.1 per 100 child years. The reason for low incidence of disease in children is not well understood, because it has been shown that children are exposed to *Cryptococcus* at an early age as evidenced by antibody detection.

### Risk Factors

As with most invasive fungal infections, immunocompromised patients have the highest risk of acquiring an invasive cryptococcal infection. Typically, few patients with disease do not have HIV/AIDS or an identifiable risk factor (10%–40%), yet the recent emergence of *C gattii* infection in immunocompetent hosts in British Columbia highlights the importance of heightened vigilance and the need for a high index of suspicion in all patients.

The most important risk factors for invasive cryptococcal disease are HIV/AIDS, long-term use of steroids, solid organ transplant, hematologic malignancy,

and the use of immunomodulators. Also, patients with diabetes, sarcoidosis, CD4 lymphopenia, lymphoproliferative disease, hyper-IgM and hyper-IgE syndromes, renal failure (on peritoneal dialysis), liver disease (cirrhosis), and systemic lupus erythematosus are at increased risk for invasive disease.

Patients with HIV in particular have an increased risk for dissemination and CNS disease. These patients are more likely to have positive blood cultures, less CNS inflammation, a higher fungal burden, and increased antigen titers.

### Diagnosis

#### Signs and Symptoms

Signs and symptoms will depend on the organ infected as well as the host's immune status.

**LUNG.** Patients with cryptococcal lung infection can present with a range of symptoms, from asymptomatic (up to one-third of nonimmunocompromised patients), in which suspicion is raised based on an abnormal chest radiograph, to acute respiratory distress, which is more common in immunocompromised hosts. When presenting with nonspecific symptoms, fever, cough, chest pain, weight loss, and increased sputum production are commonly reported. Onset of disease can be insidious or acute. Immunocompromised patients tend to present with a more rapid progression, and patients with AIDS usually exhibit neurologic symptoms caused by dissemination at the time of diagnosis. Patients infected with *C gattii* will often present with cryptococcomas in the brain. When pulmonary disease is detected, further workup must be undertaken to evaluate for the presence of disseminated disease, and a lumbar puncture must be considered for the evaluation of CNS disease (especially in immunocompromised patients).

**CENTRAL NERVOUS SYSTEM.** Presentation can be acute or subacute. Symptoms of meningitis and meningoencephalitis are common, with headache, fever, cranial nerve palsies, lethargy, coma, and memory loss commonly seen. Alternatively, severe intermittent headaches may be the only symptom, and a few cases can present solely with altered mental status. CNS disease carries a high risk of concomitant elevated intracranial pressure (ICP), most commonly among patients with AIDS. In contrast, non-HIV-infected patients carry a higher risk of an inflammatory meningeal reaction and an increased likelihood of cryptococcomas. Cryptococcomas are also more common in patients infected with *C gattii*.

**PROSTATE.** Prostatic infection typically presents with symptoms of prostatitis, such as frequency, urgency, and dysuria. The prostate is viewed as a site for fungal sequestration. In some instances, relapse is thought to occur when viable organisms are dispersed from the prostate after successful antifungal therapy. Dissemination has also been reported after urologic procedures whereby instrumentation leads to seeding of the yeast.

**EYE.** Before the HIV/AIDS epidemic, CNS disease was associated with eye involvement approximately 45% of the time. Currently, eye disease occurs less frequently. Ocular nerve palsies, papilledema, and retinal disease have been described. Blindness may ensue either by direct fungal invasion of the optic nerve or by damage caused by elevated ICP.

**BONE.** Bone invasion is estimated to occur in approximately 5% to 10% of cryptococcal infection, predominantly because of dissemination of the yeast. Patients can present with pain and swelling, but invasion is commonly detected on unrelated radiographic images.

**BLOOD.** Cryptococcemia is typically seen in the setting of a severely immunocompromised state, for example, in patients with AIDS with a high yeast burden.

**SKIN.** Skin lesions are primarily a noninvasive form of cryptococcal infection, yet in the immunocompromised host, skin involvement usually results from disseminated infection. Noninvasive disease typically presents with a solitary lesion in an immunocompetent patient with environmental exposure to the yeast. When occurring as a result of dissemination, skin lesions may be papular or maculopapular, typically with a soft ulcerated center, often resembling molluscum contagiosum.

**IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME.** Two forms of immune reconstitution inflammatory syndrome (IRIS) exist: unmasking and paradoxical. Unmasking refers to the onset of cryptococcal disease symptoms after successful improvement of the immunocompromised state (eg, initiating HAART, decreasing immunosuppression in solid organ transplant recipients) in patients not known to be infected with the yeast. Paradoxical IRIS refers to the reappearance of old symptoms or the emergence of new symptoms while taking appropriate antifungal therapy after successful improvement of the immunocompromised state (eg, initiating HAART, decreasing immunosuppression in solid organ transplant recipients). Classic manifestations of IRIS in *Cryptococcus* infection appear as exaggerated inflammation (eg, fever, peripheral and mediastinal lymphadenopathy, and CNS signs/symptoms). With paradoxical IRIS, cultures for *Cryptococcus* will remain negative; this is not treatment failure or relapse, but a consequence of an overwhelming host response after an improvement in the status of the immune system. *Cryptococcus*-associated IRIS has been well described in 3 distinct populations: patients with HIV/AIDS, patients with organ transplants, and postpartum women.

### Differential Diagnosis

Pulmonary disease must be differentiated from malignancy (often the disease is diagnosed after a biopsy performed for suspicion of malignancy). Also, other infectious etiologies must be ruled out, such as *P. carinii*, mycobacteria (tuberculous and nontuberculous), and *Nocardia*. Coinfection with other organisms can occur. Skin infection must be differentiated from *Histoplasmosis*, *Coccidiomycosis*, and *Penicillium* with a biopsy.

### Laboratory Findings

Diagnosis of *Cryptococcus* infection can be made with direct examination, culture, antigen testing, or PCR. Visualization of the capsule with India ink in the CSF (Figure 254-4) is diagnostic in approximately 30% to 50% of patients without AIDS and 80% of those with AIDS. *Cryptococcus* will appear as a poorly stained gram-positive organism. Other special stains that can be used on histopathology specimens include Calcofluor white, hematoxylin and eosin (H&E), mucicarmine,

Alcian blue, Fontana-Masson, and Gomori methenamine silver (Figure 254-5).

Current blood culture methods are adequate for detection of *Cryptococcus*, with growth typically seen in 3 to 7 days, though sometimes a longer incubation time is required. *Cryptococcus* can also be identified with biochemical tests and antibody positivity (although the latter exhibits poor sensitivity and specificity). PCR technology is being developed to aid in the diagnosis of infectious diseases. To date, no FDA-approved PCR test for the detection of *Cryptococcus* exists, but there are some homegrown and commercial tests available demonstrating excellent sensitivity and specificity.

One of the most commonly used methods for the diagnosis of invasive disease is antigen detection. Three different assays exist: latex agglutination, an enzyme immunoassay (EIA), and lateral flow assay (approved in July 2011). These assays can be used on CSF and serum samples. The sensitivities of the antigen detection methods depend on the host's immune status, the type of disease, and the kit used. Also,

**Figure 254-4** *C. neoformans* using a light India ink staining preparation. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

**Figure 254-5** Cryptococcosis of lung in patient with AIDS (methenamine silver stain). (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

when appropriate, caution must be taken, because the prozone effect has been well described in these assays (manage by dilution of the specimen). For the latex agglutination assays, sensitivity reaches 100% in patients with AIDS regardless of location of disease, whereas in HIV-negative patients with pulmonary disease, sensitivity can be as low as 56%. Overall specificity of the test is 93% to 98%. The EIA has a reported sensitivity of 93% to 100% and a specificity of 96% to 98% across serum and CSF samples in patients with HIV. These assays, when handled properly, have a low false-positive rate (can occur in the presence of rheumatoid factor or may cross-react with *Trichosporon*). False-negative results may be seen early in infection or in chronic indolent disease. The lateral flow assay has demonstrated CSF sensitivity and specificity greater than 99%, and serum sensitivity of 92% in HIV-infected patients with cryptococcal meningitis. More studies are needed with this detection assay. Thus far, this assay appears promising, especially in resource-limited countries, because it is cheaper and less labor intensive and provides results within minutes. Antigen detection assays can provide titer quantification, whereby a higher titer is associated with a higher burden of yeast, yet no correlations with outcomes have been made.

Several methods are available to differentiate among serotypes. Antibodies to capsules can be assessed, but this method is not very sensitive or specific and not commercially available. Biochemical tests can be used and serotypes B and C can be differentiated because they assimilate glycine, whereas serotypes A and D do not. Canavanine glycine bromothymol blue agar can be used to distinguish *C neoformans* variant *neoformans* from *C gattii*. Growth and a color change to medium blue will occur with *C gattii*, whereas little to no growth with yellow or green color is indicative of *C neoformans* variant *neoformans*. Lastly, molecular tests have been developed, but they lack standardization. These tests are also expensive and not readily available; work is in progress to standardize and facilitate them.

### Imaging

Chest imaging with lung disease is not specific and most commonly demonstrates a noncalcified node or multiple nodules. Other presentations include infiltrates, hilar adenopathy, cavitations, and pleural effusions. Immunocompromised hosts tend to have alveolar and interstitial findings more often.

In the setting of CNS disease, cryptococcomas may be seen on CT as small ring-enhancing lesions. Non-enhancing pseudocysts can also be seen on CT, most commonly in immunocompromised hosts. Hydrocephalus can be seen as a complication of meningitis.

Bone lesions typically present as lytic lesions with or without cold abscesses.

## Management

### Treatment Approach

The goal of therapy in CNS and disseminated disease is rapid sterilization; in pulmonary disease, the goal of treatment is control of signs and symptoms and

prevention of dissemination. Initiation of antifungal therapy must accompany assessment of underlying host risk factors with appropriate corrections. Treatment is targeted toward the type of infection, with duration of therapy also dictated by disease and host factors.

The following recommendations are extracted from the *Clinical Practice Guidelines for the Management of Cryptococcal Disease: 2010*, published by the IDSA. It is important to note that recommendations for treatment in children are extrapolated from adult data.

### Specific Therapy

**PATIENTS WITH HIV INFECTION.** Treatment of all forms of invasive *Cryptococcus* disease in HIV-infected individuals involves a 3-step approach: induction, consolidation, and maintenance. Induction includes amphotericin B deoxycholate (liposomal formulations can be used in patients who do not tolerate the conventional formulation) plus flucytosine for at least 2 weeks; this combination was demonstrated to be the quickest fungicidal regimen. Consolidation then follows with at least 8 weeks of high-dose fluconazole. Amphotericin B monotherapy can be used as induction therapy (when flucytosine is not available or not tolerated) for 4 to 6 weeks. Alternatively, amphotericin B plus high-dose fluconazole for 2 weeks can be used as induction therapy. High-dose fluconazole plus flucytosine is another alternative, but must be used for 6 weeks before starting consolidation therapy. When fluconazole monotherapy is used, high-dose therapy for 10 to 12 weeks is recommended for induction and consolidation. For the maintenance phase, fluconazole is recommended. Itraconazole is a less desirable alternative, and weekly amphotericin B infusions can be used in those who are unable to tolerate azoles.

For patients not receiving prior antiretroviral therapy, institution of HAART should be delayed for 2 to 10 weeks after the start of antifungal therapy to decrease the risk of IRIS. In adults, after 12 months of antifungal therapy, maintenance therapy can be stopped in patients receiving HAART who have a CD4 count greater than 100 cells/mm<sup>3</sup> and an undetectable viral load for at least 3 months. A similar recommendation for asymptomatic children older than 6 years of age has been made.

**ORGAN TRANSPLANT RECIPIENTS.** Similar to HIV-infected patients, treatment of CNS, moderately severe-to-severe non-CNS, disseminated, and severe pulmonary *Cryptococcus* disease in organ transplant recipients involves a 3-step approach. Induction therapy consisting of liposomal amphotericin B plus flucytosine for 2 weeks is followed by a consolidation phase of at least 8 weeks of high-dose fluconazole. Alternatively, when amphotericin B is used as monotherapy, the induction phase is prolonged to 4 to 6 weeks. Suppressive therapy consists of fluconazole for 6 to 12 months.

Treatment of mild-to-moderate non-CNS disease (including isolated pulmonary disease) consists of higher-dose fluconazole for 6 to 12 months (for all 3 phases of treatment). Liposomal amphotericin is preferred because the majority of transplant recipients will also be receiving a calcineurin inhibitor and the

use of conventional amphotericin with this agent is associated with increased risk of nephrotoxicity. Immunosuppressive therapies should be reduced in a cautious fashion to lower the risk of IRIS.

**PATIENTS WITHOUT HIV INFECTION AND TRANSPLANTS.** Treatment of CNS, severe pulmonary cryptococcal disease, and cryptococemia in this population also follows a 3-step approach. Patients exhibiting neurologic complications should receive induction therapy with amphotericin B plus flucytosine for 6 weeks followed by consolidation with high-dose fluconazole for at least 8 weeks. Maintenance therapy with fluconazole is then used and should last for at least 6 to 12 months. Patients without neurologic complications and with sterile CSF specimens after 2 weeks of treatment can receive a shortened 4-week induction treatment with combination therapy, followed by an 8-week consolidation phase with high-dose fluconazole, then the 6- to 12-month maintenance treatment with fluconazole. Patients who do not tolerate conventional amphotericin B can be treated with a liposomal formulation instead. Alternatively, patients with excellent response after 2 weeks who are at low risk can be treated with an induction time of 2 weeks (combination therapy) followed by fluconazole (high dose for the 8-week consolidation phase and standard dose for the 6–12 months of maintenance therapy). In cases in which flucytosine is not given, not tolerated, or interrupted, amphotericin induction monotherapy should be extended by at least 2 weeks.

Mild-to-moderate pulmonary disease and single site disease (not CNS or blood) in the absence of severe immunosuppression can be treated with fluconazole monotherapy for 6 to 12 months.

When infection is caused by *C. gattii*, length of treatment is dictated by imaging results. Presence of cryptococcomas will require prolonged therapy (corticosteroids are sometimes added to therapy) in both CNS and pulmonary infections. Large cryptococcomas may need surgical excision.

**COMPLICATIONS.** In cases of persistent disease, immune status must be re-evaluated and corrected when possible. Typically, relapse is caused by inadequate primary therapy and/or poor medical therapy compliance. Drug susceptibility testing should be considered at this point, because resistance has been described, although rarely. Fluconazole MICs greater than 16 mcg/mL and flucytosine MICs greater than 32 mcg/mL reflect fungal resistance. Salvage therapy with voriconazole and posaconazole has been used with some success. Interferon- $\gamma$  has been used in conjunction with antifungal therapy as well as salvage therapy with some success.

With CNS disease, elevated ICP can occur. CSF pressure should be measured on initial lumbar puncture and should be repeated in the face of focal neurologic symptoms or impaired mentation. For persistently elevated pressures, serial (daily) lumbar punctures can be performed or placement of a lumbar drain or ventriculostomy can be considered. Permanent ventriculoperitoneal shunts are sometimes required in the setting of continued elevated pressures and can be placed during an active infection if clinically necessary.

### When to Admit

Children with an invasive *Cryptococcus* infection should be admitted until clearance of the fungus is demonstrated and clinical improvement noted.

### When to Refer

Invasive *Cryptococcus* infections require complex care; consultation with an infectious disease specialist is recommended. Also, for CNS disease with increased ICP or cryptococcomas, consultation with neurosurgery is often needed.

### Ongoing Care

#### Follow-Up

Children whose cryptococcal disease is effectively treated but continue with immunosuppression should have continued prophylaxis depending on the level and extent of immunosuppression.

### Complications

Complications related to antifungal therapy may develop. Flucytosine can cause cytopenia, and drug levels should be monitored. If itraconazole is used, because of its erratic absorption, drug levels should be monitored to ensure a therapeutic range. Also, with newer agents (voriconazole and posaconazole), drug levels may need to be monitored as well (data lacking for cryptococcal disease). At times, persistence of fungal disease is encountered. When this occurs, ensure that immunodeficient states have been addressed (eg, initiation of HAART, decrease of immunosuppressants) and extend the induction phase. Also, doses of antifungal agents may need to be increased and a change in agent may be necessary. Determining the susceptibility profile is sometimes needed, although generally *Cryptococcus* is susceptible to amphotericin B, flucytosine, and fluconazole. Also, with CNS disease, eye involvement leading to blindness may occur. Another complication of CNS disease is an elevated ICP, which may require specific therapy. Another complication often seen is IRIS. No change in therapy is required, but with severe CNS symptoms (CNS inflammation with increased ICP), corticosteroids could be considered. CNS disease can involve the development of cryptococcomas; in such cases, treatment is prolonged as previously described. Corticosteroids are sometimes needed in the setting of mass effect and surrounding edema. Pulmonary disease can result in acute respiratory distress syndrome; supportive care is needed and corticosteroid therapy is sometimes warranted.

### Prognosis

*Cryptococcus* mortality assessments vary within geographic/economic regions. In high-income regions a 9% mortality rate is described; in low-to-middle-income regions, a 55% mortality rate is described; and in sub-Saharan Africa, a 70% mortality rate is described. In Zambia, a 2001 study showed a 100% 6-month mortality rate using fluconazole monotherapy. During the 1999–2007 *C. gattii* outbreak reported in Vancouver, British Columbia, an 8% case-fatality rate was reported. Globally, in patients with HIV/AIDS, cryptococcal meningitis is responsible for an average of 600,000 deaths within 3 months of infection.

### Prevention

In adults with HIV who live in *Cryptococcus*-endemic areas or have a high occupational risk, fluconazole prophylaxis is recommended when the CD4 count is less than 150 cells/mm<sup>3</sup>. In contrast, no such recommendation exists for children with HIV, because of the low incidence of disease. Further studies are needed to determine antigen and antibody reactions to formulate a vaccine that will provide a balanced level of protection for individuals with differing immune statuses.

## GLOMEROMYCETES

### Etiology

Glomeromycota is a phylum belonging to the fungi kingdom. With advances in molecular mycology, taxonomy of the Glomeromycota has been updated. Previously, phylum Zygomycota contained 8 orders, including the orders Mucorales and Entomophthorales. Taxonomic revisions have led to the abolition of phylum Zygomycota, and the creation of 4 subphyla within the Glomeromycota. Relevant to human disease are subphyla Mucormycotina (orders Mucorales and Mortierellales) and Entomophthoramycotina (order Entomophthorales). Of the Glomeromycota, members of the order Mucorales cause most human disease; this disease is commonly referred to as *mucormycosis*.

Glomeromycosis produces aseptate or pauciseptate hyphae and reproduces both sexually and asexually with the formation of zygospores (Figure 254-6). These spores are small and easily aerosolized; inhalation of the spores is the primary mechanism of infection. The hyphae form is responsible for angioinvasion and dissemination, which are characteristic of mucormycosis tissue infections.

### Epidemiology

Mucormycetes are found throughout the environment, commonly in spoiled matter such as bread, fruits, vegetables, and soil. They can also be found in animal excreta and can colonize environmental surfaces such as bandages, needles, and tongue depressors; nosocomial cases have been linked to contact with these contaminated objects. Also, there may be an association with

extremes of weather: following hurricanes Katrina and Rita, a cluster of infections with a rare *Mucor* species, *Syncephalastrum*, was reported. Similarly, following a tsunami in Southeast Asia, wound infection with *Apophysomyces elegans* was described. In 2011, following a tornado in Joplin, Missouri, multiple cases of cutaneous mucormycosis caused by *Apophysomyces* were reported.

Mucormycosis follows *Candida* and *Aspergillus* as the third most common cause of invasive fungal infection, yet the true incidence of invasive mucormycosis is not known. In the United States, the annual incidence of mucormycosis was estimated by Rees and colleagues to be 1.7 cases per million people, equaling approximately 500 cases a year. In France, an incidence of 1.2 per million people was reported in 2002. Notably, an increase in mucormycosis was reported in high-risk patients treated or receiving prophylaxis for *Aspergillus* infection with voriconazole (an azole antifungal with no activity against mucormycetes). Organisms belonging to the subphylum *Mucorales* are the most commonly reported Glomeromycetes causing human disease. *Rhizopus*, followed by *Mucor*, were the most prevalent in a review of 929 clinical cases. Organisms from the family *Cunninghamella* followed. Members from the subphylum Entomophthorales accounted for approximately 7% of isolated Glomeromycetes in the same review.

Entomophthoramycotina typically cause skin and subcutaneous tissue disease. Organisms include *Conidiobolus* and *Basidiobolus*. These fungi are commonly found in soil worldwide, yet most cases of infection are located in tropical Africa, South America, Central America, and Asia. *Basidiobolus* was recently described as causing gastrointestinal disease in patients in the United States.

As with most invasive fungal infections, despite multiple medical advances, treatment of infection has not progressed much and the mortality of invasive mucormycosis remains high (~50%). In children, mortality approaches 90% without treatment, but decreases to 36% with appropriate therapy. Site of disease and age prove to be important determinants of mortality. In a study in children, cerebral and gastrointestinal disease were associated with a 100% mortality rate, disseminated disease was associated with an 88% mortality rate, and cutaneous disease showed a 0% mortality rate. Another review showed a mortality rate of 64% in neonates and 56% in children, compared with 53% in adults.

Five common forms of invasive mucormycosis are described—rhinocerebral, pulmonary, gastrointestinal, disseminated, and cutaneous—as well as a few uncommon presentations.

### Risk Factors

Persons who are malnourished, those with poorly controlled diabetes mellitus, metabolic acidosis, trauma, and persistent neutropenia, as well as iron-overloaded patients (especially those receiving deferoxamine therapy) have an increased risk of invasive mucormycosis. High-risk transplant recipients (bone marrow and solid organ), especially those receiving steroid therapy, also have an increased risk of invasive mucormycosis.

**Figure 254-6** This photomicrograph reveals a number of young sporangia of a *Mucor* spp fungus. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

Phagocytosis is an integral part of the host defense against mucormycetes. Neutropenic patients lack sufficient cells to effectively kill the fungus. Steroids impair the migration and phagolysosome function of macrophages. Similarly, patients with diabetic ketoacidosis demonstrate impaired neutrophil chemotaxis. Deferoxamine is of special mention: its use supports invasive mucormycosis because this agent acts as a siderophore for Mucorales.

Infection most often occurs after inhalation of the small-aerosolized spores, thus most infections occur in the sinuses and/or lungs. In immunocompetent hosts, direct inoculation is a more common portal of entry. Rarely, ingestion of spores can be the source of infection. The site of disease also differs by host status; rhinocerebral disease is the most common type of infection in diabetic patients. Transplant recipients and patients with malignancy are more likely to present with pulmonary disease. Patients receiving injected drugs tend to present with cerebral disease, whereas healthy hosts typically present with cutaneous lesions. Those receiving deferoxamine therapy commonly present with pulmonary, rhinocerebral, or generalized disease.

## Diagnosis

### Signs and Symptoms

Presentations of invasive disease depend on the site of infection and upon host factors.

**RHINOCEREBRAL INFECTIONS, INCLUDING RHINOSINUSITIS, PANSINUSITIS, RHINO-ORBITAL DISEASE, AND RHINOCEREBRAL INFECTION.** Symptoms of the various rhinocerebral infections often overlap; commonly reported ones include facial pressure, nasal obstruction and/or congestion, epistaxis, headache, mouth pain, otologic symptoms, hyposmia/anosmia, and fever. The presence of cough suggests that lung involvement has occurred. The angioinvasive nature of the fungus may lead to rapid development of necrosis (an eschar) in the area involved. Rapid progression with extension to the orbits (eyelid edema, chemosis, ptosis, proptosis with ophthalmoplegia) and the brain (epidural and subdural abscesses as well as cavernous and sagittal sinus thrombosis) can occur.

**PULMONARY.** Patients typically present with persistent fever despite broad-spectrum antimicrobial therapy, as well as with nonproductive cough, pleuritic chest pain, and dyspnea. In some cases, chest wall cellulitis can occur. With angioinvasion of large blood vessels, hemoptysis can occur.

**GASTROINTESTINAL.** Gastrointestinal invasive mucormycosis is uncommon and is rarely diagnosed antemortem. In gastrointestinal mucormycosis, ingestion of the spores in extremely malnourished patients and in those with severe systemic illness and systemic immunosuppression leads to disease. In neonates, the presentation will resemble necrotizing enterocolitis, whereas neutropenic patients typically develop a masslike lesion near the appendix or ileum. Neutropenic fever, typhilitis (neutropenic enterocolitis), and hematochezia can also be presenting symptoms.

**DISSEMINATED.** Antemortem diagnosis of disseminated mucormycosis is also rare. Symptoms are nonspecific and rapidly progressive. Pneumonia is common, as is brain involvement.

**SKIN AND SOFT TISSUE.** This spectrum of infection is primarily noninvasive, especially in the healthy host. However, in neutropenic patients who continue to be immunosuppressed, disseminated disease may ensue. Typically, an area of cutaneous erythema and induration develops, which may progress to involve the subcutaneous tissue and bone. Necrotizing fasciitis occurs rarely.

**OTHER.** Less commonly invasive presentations of mucormycosis include peritonitis, tracheitis, mediastinitis, endocarditis, and brain abscesses. Peritonitis has been described in patients who receive continuous ambulatory peritoneal dialysis with history of a prior or concurrent central line infection.

### Differential Diagnosis

Rhinocerebral disease presents similarly to other causes of sinusitis with the exception of the characteristic angioinvasive progression and extension to nearby structures. The absence of necrosis early in the disease course of a high-risk host does not eliminate mucormycosis as a diagnostic possibility.

Pulmonary disease caused by mucormycetes is virtually indistinguishable from invasive pulmonary aspergillosis, especially in patients with hematologic malignancies. The presence of concomitant pansinusitis, history of prophylactic drug use against *Aspergillus* (and not mucormycetes), and the lack of a positive *Aspergillus* galactomannan antigen test result point toward mucormycosis as the cause of the fungal pulmonary disease. Gastrointestinal disease will present in the same manner as other acute intra-abdominal infectious processes, such as enteritis, appendicitis, necrotizing enterocolitis, and typhilitis. Diagnosis of skin infection caused by mucormycetes requires a biopsy.

### Laboratory Findings

Diagnosis of infections caused by mucormycetes is almost always based on histopathologic evidence of fungal tissue invasion. On histopathology stains, mucormycetes can be distinguished from other molds by their broad, thin-walled, wide-branching, and ribbon-like, mostly aseptate, hyphae. Sporangia are rarely seen in tissue. Commonly used stains include Gomori methenamine silver, periodic acid-Schiff, and Calcofluor white stains. Entomophthoromycotina can sometimes be distinguished from mucormycotina on histopathology stains, because of the presence of eosinophils surrounding the hyphae.

Culture is required to differentiate among species once a diagnosis of mucormycosis is made, because most species are morphologically similar. However, cultures are only positive about 50% of the time. To enhance growth and recovery of the mold, mincing (instead of homogenizing) tissue and incubation at less than 37°C with relative anaerobic conditions are advised. Empirical antifungal therapy should be instituted regardless of culture results, because histopathology is sufficient for diagnosis, and culture results, although desirable, are delayed and often unnecessary.

Currently, no mucor-specific serology tests are available. Molecular testing using PCR assays for mucor nucleic acid is available at few research institutions; however, further studies are needed before

PCR-based fungal diagnostic tests can be validated and made available commercially.

### Imaging

In rhinocerebral disease, CT and MRI of the brain and sinuses usually reveal patterns suggestive of sinus disease: mucosal thickening, air-fluid levels, and bony erosion. Orbital mucosal thickening may be visualized, and is usually detected earlier on MRI than on CT. Thickening of the extraocular muscles can also signify orbital infection. Serial imaging is necessary to monitor disease progression and treatment response.

In pulmonary disease, chest radiographs may show lobar consolidation, nonspecific infiltrates, masses, nodules, and even cavities; frequently, the upper lobes are affected. Following angioinvasion, wedge-shaped areas of infarction can be seen. CT can show disease before a radiograph, usually presenting as multiple nodules and pleural effusions. Also, similarly to invasive aspergillosis, halo and air crescent lesions can be seen on CT.

### Management

#### Treatment Approach

Treatment of mucormycosis should begin as soon as disease is suspected and before a definitive diagnosis is made. Combined surgical and antifungal therapy is most often used. Surgery is paramount; because of the angioinvasive nature of the mucormycetes, antifungal agents often fail to penetrate infected tissue effectively.

Current treatment guidelines are based on case reports and data reviews of adult disease. Induction therapy with high-dose amphotericin B (a liposomal preparation is preferred) for 3 weeks followed by a prolonged course with posaconazole (if tolerated) is the current suggested regimen. Further, addition of an echinocandin (anidulafungin, caspofungin, micafungin) for combination therapy during induction is recommended by some experts. Glomeromycetes are intrinsically resistant to echinocandins, yet animal studies have demonstrated fungal killing synergy when echinocandins are used in combination with a polyene antifungal; this combination therapeutic approach has been supported by clinical reports.

During induction antifungal therapy, workup should be continued to evaluate the extent of fungal disease. Also, whenever possible, surgical excision of the affected tissues should be performed. In children, appropriate antifungal therapy reduces the risk of death by 92%, and surgery reduces the risk by 84%. Immunosuppression and hyperglycemia should be evaluated and corrected whenever possible.

Following induction therapy, posaconazole can be used for the remainder of the treatment course provided the patient's condition has improved and the drug is tolerated. Posaconazole oral suspension exhibits erratic absorption, but the delayed-release tablet and intravenous formulation deliver reliable serum drug levels. When the oral suspension is used, therapeutic drug monitoring may be necessary though clear values have not yet been defined (concentration greater than 1 mcg/mL is generally sought). It may be prudent to provide an overlap in treatment with amphotericin (with or without an echinocandin) and posaconazole until therapeutic posaconazole levels are attained.

When there is insufficient response to therapy, the dose of amphotericin B can be increased. Consideration may also be given to administration of granulocyte-macrophage colony stimulating factors and/or interferon- $\gamma$ . Hyperbaric oxygen is yet another supplemental therapy that can be used, mostly in cutaneous disease. Deferasirox, an iron chelator shown not to act as a siderophore (unlike deferoxamine), had shown promise, yet a recent phase II trial showed a higher mortality rate at 90 days with deferasirox treatment. Further studies are warranted given the limited sample size and imbalances of underlying disease at randomization in this study. Nonetheless, treatment with deferasirox is not currently recommended as first-line therapy for the treatment of mucormycosis.

### Specific Therapy

Antifungal therapy should be initiated at the first serious suspicion of mucormycosis, before confirmation of disease, because early presumptive therapy is associated with improved clinical outcomes. A significant increase in mortality with the delay of effective therapy has been described.

Standardized antifungal susceptibility testing has shown that Glomeromycetes are generally susceptible to amphotericin B and posaconazole, and are resistant to most other antifungal agents currently available. Current antifungal treatment of mucormycosis is amphotericin B alone or in combination with other agents previously described. Duration of therapy is not defined; most therapeutic courses are tailored individually, and use radiographic resolution and immune reconstitution as therapeutic endpoints.

### When to Admit

All children with suspected or proven mucormycosis should be admitted for aggressive evaluation and empirical therapy until demonstration of clearance and clinical improvement.

### When to Refer

All children with suspected or proven mucormycosis should be approached with a multidisciplinary team, including infectious disease specialists, ophthalmologists, otorhinolaryngologists, neurosurgeons, and clinical pharmacists.

### Ongoing Care

#### Follow-Up

Patients who recover from invasive mucormycosis infection and continue to require immunosuppression may benefit from antifungal prophylaxis with an anti-mucormycosis agent such as posaconazole. As noted before, patients receiving oral suspension posaconazole therapy should undergo regular therapeutic drug monitoring. Also, many patients who survive rhinocerebral diseases will have undergone disfiguring debridement surgeries. Such patients will require intensive psychological support. Reconstructive surgery, when possible, should be considered.

### Complications

Complications of mucormycosis are related to both disease and treatment. Severely immunocompromised patients and those with erosive disease will experience tissue damage, as a consequence of infection as

well as surgical management. Sometimes wide resections are necessary to control progressive disease. In the case of cutaneous disease, the innate integument barrier may further break down. The prolonged and high doses of antifungal agents also pose risks of complications, most notably renal and hepatic toxicity, and Q-T interval prolongation.

### Prognosis

Early treatment of suspected mucormycosis is essential; delayed therapy is associated with a twofold increase in the 12-week mortality rate. Mucormycosis survival is multifactorial because disease site, underlying host factors, and age can affect outcomes. In children, overall mucormycosis mortality, despite appropriate therapy, is 36% to 56%. One review demonstrated 62% survival in adults treated with antifungal therapy and 57% survival in patients treated with surgery, whereas patients treated with a combination of surgery and antifungal therapy had a 70% survival rate.

### Prevention

Prevention of mucormycosis is primarily directed at reducing risk factors, including controlling diabetes, using chelating agents other than deferoxamine to treat iron overload, and, when possible, reducing or correcting immune suppression. It should be noted that an increase in mucormycosis has been reported in high-risk patients. This increased rate of mucormycosis correlates with the introduction of voriconazole as prophylaxis against *Aspergillus* infections. Fortunately, mucormycosis remains a rare disease. As a consequence of the rarity of mucormycosis, routine antifungal prophylaxis directed against the mucormycetes is not generally indicated, even among high-risk patients.

## HISTOPLASMOSIS

### Etiology

The dimorphic fungus *Histoplasma capsulatum* causes histoplasmosis. *H. capsulatum* grows in the environment in the mycelial (mold) form and converts to the yeast form in tissues at body temperature.

### Epidemiology

In the United States, *H. capsulatum* is endemic mostly in the central and southeastern states, along the Mississippi, Ohio, and Missouri river valleys. Internationally, *H. capsulatum* is found predominantly in eastern and southern Europe, parts of Africa, eastern Asia, and Australia. In epidemiologic studies, skin test reactivity against *H. capsulatum* commonly develops in people residing in hyperendemic areas. The mycelial form is found in moist soil, with growth facilitated by droppings of bat, bird, and chicken.

### Risk Factors

Infections occur sporadically or in outbreaks, and are associated with aerosolization of spores (Figure 254-7), typically under dry and windy weather conditions. Endemic area activities that have been linked to development of infection include gardening activities; playing in barns, hollow trees, caves, or bird roosts; excavation; and demolition, cleaning, or renovation of

**Figure 254-7** Asexual spores (conidia) of *Histoplasma capsulatum*. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

**Figure 254-8** Computed tomography scan of lungs showing classic snowstorm appearance of acute histoplasmosis. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

contaminated buildings. Person-to-person transmission of histoplasmosis does not occur. The severity of illness depends on the extent of exposure, size of inoculum, strain-specific virulence, and host immune status.

### Diagnosis

#### Signs and Symptoms

Infection with *H. capsulatum* has a wide spectrum of clinical manifestations. Symptomatic infection occurs in fewer than 5% of infected individuals. Based on the site, duration, and pattern of infection, histoplasmosis is classified into 3 types: acute pulmonary infection (Figure 254-8), chronic pulmonary histoplasmosis, and progressive disseminated histoplasmosis.

As noted before, more than 90% of patients with acute pulmonary infection are asymptomatic. For patients who become symptomatic, the incubation period for histoplasmosis is usually 1 to 3 weeks after exposure. Symptomatic disease occurs more commonly in

young children or in older adults. The prodrome of histoplasmosis is a flulike illness with fever, cough, headache, malaise, myalgia, abdominal pain, and chills. Intense exposures can cause diffuse pulmonary involvement, causing severe dyspnea. Asymptomatic pleural effusions can be present in up to 10% of infected individuals. Pericarditis and enlarged hilar and mediastinal lymph nodes are present in 5% to 10% of patients. Joint pain and skin lesions such as erythema nodosum occur most frequently in women and adolescents.

Chronic pulmonary histoplasmosis, an opportunistic infection encountered in the adult population, is rare in children. Pathologically, chronic histoplasmosis is characterized by centrilobular emphysema.

Progressive disseminated histoplasmosis can develop in healthy infants and children younger than 2 years of age. Fever can be present for weeks before the diagnosis is made. Other signs of progressive disseminated histoplasmosis in infants include failure to thrive and massive hepatosplenomegaly. If untreated, progressive disseminated histoplasmosis is followed by diffuse adenopathy, pneumonia, mucosal ulceration, pancytopenia, disseminated intravascular coagulopathy, and gastrointestinal tract bleeding. Meningitis occurs in about 60% of infected infants. Immunocompromised patients with cellular immune dysfunction can develop progressive disseminated histoplasmosis followed by acute pulmonary infection. Progressive disseminated histoplasmosis is an AIDS-defining illness in an HIV-infected individual.

### Differential Diagnosis

The differential diagnosis of symptomatic pulmonary histoplasmosis includes blastomycosis, coccidioidomycosis, and tuberculosis. Noninfectious etiologic considerations with mediastinal/hilar lymphadenopathy are lymphoma and sarcoidosis. Progressive disseminated histoplasmosis with pancytopenia, hepatosplenomegaly, and gastrointestinal hemorrhage can mimic reticuloendothelial or primary gastrointestinal tract neoplasm. Because severe disseminated histoplasmosis can be an opportunistic infection, screening for immunodeficiency disorder is warranted in an otherwise healthy individual infected with disseminated disease with no known risk factors.

### Laboratory Findings

Culture, serologic tests, tissue and body fluid examination, and EIA for *Histoplasma* antigen in the urine, serum, CSF, and bronchoalveolar lavage fluid are the principal laboratory specimens used for diagnosis.

Despite a long turnaround time, isolation of *Histoplasma* in culture is the definitive method of diagnosis. Culture specimens can be obtained from blood, bone marrow, sputum, and tissue. The sensitivity of the culture differs with type of infection, with the lowest sensitivity seen with acute pulmonary infection and highest sensitivity with progressive disseminated histoplasmosis. In the face of clinical suspicion, demonstration of typical intracellular yeast forms in the specimen using Gomori methenamine silver or other stains strongly supports the diagnosis of histoplasmosis.

Complement fixation and immunodiffusion assays are used for serologic diagnosis of histoplasmosis. These tests are positive in about 90% of cases in nonimmunocompromised patients. The titer of the complement fixation test is directly proportional to the degree of exposure and severity of illness. The complement fixation test is more sensitive but less specific than the immunodiffusion test because of assay cross-reactivity with other fungal antigens. In the immunodiffusion precipitin test, H bands are more suggestive of active infection than M bands.

Detection of *H capsulatum* galactomannan antigen in body fluids using a quantitative EIA is the most rapid and widely available diagnostic test for histoplasmosis. The *H capsulatum* galactomannan assay is sensitive in early primary pulmonary infection in patients with progressive dissemination, and is especially useful for diagnosis of histoplasmosis in immunocompromised patients with negative antibody titers. Because the test is not 100% sensitive, a negative test result does not exclude infection. Once positive, the antigen *H capsulatum* galactomannan assay is also useful in monitoring treatment response and relapse. Assay cross-reactivity is high with blastomycosis, coccidioidomycosis, and paracoccidioidomycosis infection.

### Imaging

Most children with acute pulmonary histoplasmosis have normal chest radiographs. Symptomatic patients typically have a patchy bronchopneumonia with variable hilar lymphadenopathy. There can be incidental findings of single or multiple calcified nodules in the lungs and hilar lymph nodes of asymptomatic residents of endemic regions. Chest CT is more sensitive than plain radiography. Depending on the level of exposure, a diffuse reticulonodular infiltrate can be observed.

### Management

#### Treatment Approach

Most *Histoplasma* infections in immunocompetent individuals are self-limiting and do not require treatment. Progressive disseminated histoplasmosis is the only disease manifestation requiring therapy in an otherwise immunocompetent child. Other indications for treatment include prolonged symptomatic infection (>4 weeks), seriously ill patients, obstructive granulomatous adenitis, and acute infection in immunocompromised individuals. Isolated pericarditis, presumed ocular disease, and rheumatologic syndromes do not require antifungal therapy. Fibrosis of mediastinal structures is not responsive to antifungal therapy.

#### Specific Treatments

Amphotericin B is recommended by the IDSA for disseminated disease and other serious infections in children. Azole antifungals can be used either after induction with amphotericin B or as monotherapy in mild or moderate disease. Itraconazole is preferred over fluconazole because of its effectiveness, better toxicity profile, and lower potential for induction of resistance.

For treatment of severe acute pulmonary histoplasmosis, amphotericin B followed by itraconazole for 12 weeks is recommended by the IDSA and the

American Academy of Pediatrics (AAP). Mild to moderate pulmonary infection persisting for longer than 4 weeks may require oral itraconazole for 6 to 12 weeks. Obstructive mediastinal adenitis requires concomitant use of a short course of corticosteroids with 6 to 12 weeks of itraconazole. For disseminated infection, amphotericin B may be given initially for 4 to 6 weeks followed by oral itraconazole maintenance therapy for 6 to 18 months (the duration of itraconazole therapy is determined by clearance of *Histoplasma* galactomannan). Patients with HIV with disseminated histoplasmosis require lifelong suppressive therapy with itraconazole.

### When to Admit

All immunocompromised children infected with *Histoplasma*; all children with severe acute pulmonary infections requiring intravenous therapy and supplemental oxygen; and all children with acute progressive disseminated histoplasmosis, regardless of immune status, should be admitted.

### When to Refer

All suspected or proven cases of histoplasmosis should be referred to infectious disease specialists. Disseminated histoplasmosis in an otherwise healthy child warrants referral to an immunologist.

### Ongoing Care

#### Follow-Up

All patients with histoplasmosis should be monitored periodically. Acute progressive disseminated histoplasmosis is associated with a high relapse rate especially among patients with AIDS. Histoplasmosis antigen is useful to monitor for relapse. A systemic evaluation should be conducted in cases of relapse.

### Complications

Acute progressive disseminated histoplasmosis is associated with overwhelming sepsis syndrome with disseminated intravascular coagulation, gastrointestinal bleeding, nephrocalcinosis, and hypercalcemia. Adrenal insufficiency develops in 5% to 10% of patients with subacute pulmonary disseminated histoplasmosis, regardless of treatment. Presumed ocular histoplasmosis, mediastinal fibrosis, chronic histoplasmosis, and endocarditis are manifestations that occur almost exclusively in adults.

### Prognosis

Acute pulmonary histoplasmosis usually has a good outcome. Acute progressive disseminated histoplasmosis is fatal without treatment and is associated with a relapse rate of 50% among treated individuals. In patients with *Histoplasma* meningitis, cure rates are only 50%, with a high rate of disease relapse. Chronic progressive disseminated histoplasmosis has a waxing and waning course. Intervening asymptomatic periods can last for years. If untreated, subacute progressive disseminated histoplasmosis results in death within 2 to 24 months.

### Prevention

Individuals traveling to or residing in endemic areas should be educated about minimizing exposure and

high-risk activities. For unavoidable activities, protective respiratory masks should be used. Decontaminating infected soil with a 3% formalin solution can prevent aerosolization of conidia.

## BLASTOMYCOSIS

### Etiology

Blastomycosis is caused by *Blastomyces dermatitidis*, a thermal dimorphic fungus that exists in the yeast form at 37°C in infected tissues, and as a white mold in the environment. The conidia, produced by mold form, convert to yeast and are infectious to humans.

### Epidemiology

The incidence of blastomycosis in children is low, constituting 2% to 10% of reported cases. The disease is endemic to the midwestern, north central, and south-eastern parts of the United States, with most cases seen in areas surrounding the Mississippi and Ohio rivers and the Great Lakes. Internationally, blastomycosis has been reported in Canada, India, Africa, and Central and South America.

### Risk Factors

Hunters or forestry workers in wooded endemic areas are at highest risk for infection.

### Diagnosis

#### Signs and Symptoms

The spectrum of disease ranges from asymptomatic infection to acute, chronic, or fulminant disease. The major clinical manifestations of blastomycosis are pulmonary diseases, cutaneous diseases, and disseminated infection. Acute pulmonary infection is the most common clinical manifestation of blastomycosis in children. Severity of respiratory symptoms varies from person to person. Symptoms of chronic pneumonia include weight loss, night sweats, cough, and fever (mimicking tuberculosis) and can persist for months. Extrapulmonary or disseminated disease usually follows pulmonary infection. The most common sites of dissemination of *Blastomyces* infection are skin, bone, CNS, and the genitourinary system. The cutaneous lesions caused by *Blastomyces* vary in morphology from nodular and verrucous to ulcerative (Figure 254-9). Bone infection has been reported in 25% to 50% of people with *B dermatitidis* infections.

### Differential Diagnosis

Acute pulmonary pneumonia caused by blastomycosis can be confused with bacterial pneumonia, especially with pulmonary tuberculosis. The typical verrucous or ulcerative cutaneous lesions may mimic skin cancers, such as basal cell carcinoma and squamous cell carcinoma.

### Laboratory Findings

Definitive diagnosis of blastomycosis requires demonstration of thick-walled, figure-of-8-shaped, broad-based, single-budding yeast in body fluids or tissue specimens by staining (10% potassium hydroxide or a silver stain) (Figure 254-10) or culture. Serodiagnosis of blastomycosis infection using complement fixation

**Figure 254-9** Nodular skin lesions of blastomycosis, one of which is a bullous lesion on top of a nodule. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

**Figure 254-10** Histopathology of blastomycosis. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

antibodies and immunodiffusion precipitin bands has poor sensitivity and specificity and significant cross-reactivity with other fungi. *Blastomyces* antigen can be detected in urine, but cross-reactivity occurs with other endemic mycoses. Therefore, negative test results do not exclude the diagnosis of blastomycosis, and every attempt should be made to obtain a tissue or body fluid specimen for staining and culture. Skin testing is unreliable because of unpredictable waning of reactivity over time. An immunoassay to measure *B dermatitidis* antigenuria is reported to have good sensitivity (93%) and specificity (79%), but the test is not available widely.

### Imaging

In patients with blastomycosis, the chest radiograph is abnormal in most cases. Radiographic findings of blastomycosis include mass lesions, nodules, cavities, pleural effusion, fibrosis, and interstitial disease. For patients with extrapulmonary blastomycosis, CT or

MRI can be helpful for detecting skeletal lesions, which are typically multiple and lytic in nature and can involve long or flat bones. Lytic lesions of vertebrae, ribs, pelvis, or skull should raise suspicion of blastomycosis.

### Management

#### Treatment Approach

Asymptomatic acute pulmonary infections are often self-limited and resolve spontaneously. For symptomatic patients with acute pulmonary infection, recommendations have shifted toward treating with antifungals for at least 3 months. Mildly ill patients who are already improving without antifungal therapy can be observed for a short time before instituting treatment. Nonetheless, a careful evaluation for extrapulmonary infection should be performed and close follow-up is needed. Systemic antifungal treatment is recommended by the IDSA for chronic pulmonary infections and for all extrapulmonary forms of blastomycosis.

#### Specific Treatments

Amphotericin B is the drug of choice for initial treatment of severely ill patients followed by completion therapy with itraconazole. For patients with CNS involvement, amphotericin B is preferred for the entire course of therapy, because azoles have a limited role in treating CNS blastomycosis. For mild to moderately severe infections, oral itraconazole or fluconazole can be used alone or after a short course of amphotericin B. Duration of therapy recommended by the IDSA and AAP is at least 6 months for pulmonary and extrapulmonary disease and 1 year for osteomyelitis.

#### When to Admit

Admit all children with severe acute pulmonary infections requiring intravenous therapy and supplemental oxygen, and all children with CNS blastomycosis.

#### When to Refer

All suspected or proven cases of blastomycosis should be referred to infectious disease specialists. For children with high clinical suspicion for blastomycosis, surgeons, pulmonologists, and interventional radiologists should be involved to obtain tissue specimens for diagnosis.

#### Ongoing Care

##### Follow-Up

Long-term follow-up is required to identify late dissemination or relapse.

#### Complications

The major complications of blastomycosis are acute respiratory distress syndrome and extrapulmonary dissemination to the skin, bones, and genitourinary system. Contractures and scarring can develop with extensive cutaneous lesions. Involvement of the CNS has been reported in 40% of adults with blastomycosis and AIDS.

#### Prognosis

Historically, mortality rates for untreated blastomycosis without antifungals exceeded 60%. Now, in

appropriately treated cases, blastomycosis mortality is less than 10%. However, for immunocompromised patients, the prognosis for acute blastomycosis remains poor despite antifungal therapy, with mortality rates as high as 30% to 40%. Most deaths from blastomycosis tend to occur during the first few weeks of therapy.

### Prevention

Immunocompromised patients residing in endemic areas should be counseled about reducing the risk of acquiring blastomycosis by avoiding high-risk occupational and recreational activities. Currently there is no vaccine available for prevention, though there has been some progress.

## COCCIDIOIDOMYCOSIS

### Etiology

Coccidioidomycosis is an infection caused by the dimorphic fungi *Coccidioides immitis* and *C posadasii*. The 2 species do not have significant morphologic, antigenic, virulence, or phenotypic differences. In the soil, both *C immitis* and *C posadasii* exist as spore-forming mycelia with branching septate hyphae. After inhalation, infectious spores (arthroconidia) produced by hyphae enlarge to form endosporeulating spherules in the tissue.

### Epidemiology

In the United States, *Coccidioides* species are endemic to the southwestern states, including California, Arizona, New Mexico, Texas, southern Nevada, and Utah. Internationally, *Coccidioides* is found in northern Mexico and in some parts of Central and South America. *C immitis* is more prevalent in California, whereas *C posadasii* is found in Mexico and areas of Central and South America.

### Risk Factors

The risk of dissemination is increased in Filipinos, blacks, pregnant women, neonates, the elderly, diabetics, and immunocompromised individuals. Seismic activity, dust storms, and archeological and recreational activities in endemic areas are major preceding events. Extensive exposure is not needed to develop infection.

### Diagnosis

#### Signs and Symptoms

The incubation period for primary pulmonary *Coccidioides* infection ranges from 1 to 4 weeks. *Coccidioides* infection is asymptomatic in approximately 60% of patients. Those with primary pulmonary infection are symptomatic with cough, fever, fatigue, myalgias, chest pain, and dyspnea. Skin manifestations may be the only symptoms in some children, and include maculopapular rash, erythema multiforme, and erythema nodosum. Erythema nodosum and arthritic symptoms are mediated by cellular immunity, and their occurrence portends a low risk of dissemination. Chronic pulmonary infections, which occur only rarely

**Figure 254-11** Pulmonary coccidioidomycosis in an adolescent girl with pulmonary cavitation. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

in children, manifest as progressive pneumonia, pulmonary nodules, and lung cavitations (Figure 254-11). Disseminated infection is uncommon in otherwise healthy children, occurring in less than 1% of infected patients. The common sites for dissemination are skin, soft tissue, joints, and lungs. Infections of the CNS most frequently involve the meninges.

### Differential Diagnosis

Because the symptoms for coccidioidomycosis are not specific, the differential diagnosis of *Coccidioides* infection is broad. Infectious causes include respiratory viral infections, bacterial pneumonias, atypical mycobacterium, tuberculosis, and other fungal infections. Noninfectious etiologic considerations include sarcoidosis, leukemias, histiocytosis, and lymphoproliferative disorders.

### Laboratory Findings

A definitive diagnosis of *Coccidioides* infection can be made by isolating the organism from normally sterile tissue sites. Specimens can be obtained from sputum, bronchoalveolar lavage fluid, blood, urine, bone marrow, lymph nodes, skin, bone, and CSF. The visualization of mature spherules containing endospores gives a presumptive diagnosis of *Coccidioides* infection (Figure 254-12). Direct examination of infected body fluids requires special staining and preparations including H&E, potassium hydroxide, or Calcofluor white. Stains of infected CSF are usually negative. If organisms are not seen with direct examination, the

**Figure 254-12** Spherule with endospores of *Coccidioides immitis* (periodic acid-Schiff stain). (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

diagnosis can be confirmed by culture. Cultures of *Coccidioides* require the use of special precautions by laboratory personnel because the mycelial form is very infectious.

Serologic tests help to confirm diagnosis and provide prognostic information, though false-negative results are possible in early infection and immunocompromised people. Most patients have IgM-specific coccidioidal antibody detectable within 10 to 21 days of being symptomatic. IgM is detected using immunodiffusion, latex agglutination test, or EIA. Though highly sensitive, the 2 latter methods lack specificity; hence positive results should be confirmed using more specific tests. The IgG response can be detected with immunodiffusion, EIA, or complement fixation (CF) test. IgG usually becomes detectable 1 to 3 months after infection. Higher CF titers ( $\geq 1:16$ ) are correlated with severity of the disease and are present in disseminated infections. Titers decrease with effective therapy and increase with disease progression. With meningeal involvement, CF is detected in CSF specimens of most patients.

The *Histoplasma* antigen EIA has been used to aid in diagnosis of coccidioidomycosis in endemic areas secondary to high cross-reactivity. However, a specific recently developed *Coccidioides* antigen EIA has higher sensitivity and specificity.

Skin testing has been used historically but is no longer available in the United States.

### Imaging

The chest radiograph of a patient with primary coccidioidomycosis can be normal or may have parenchymal infiltrates or effusions resembling viral or bacterial pneumonia. Unlike most acute pneumonias, hilar adenopathy is frequently seen with *Coccidioides* infection. Chronic pulmonary changes include thin-walled cavities, nodules varying in number and size,

and fibrosis. For detection of bony lesions, bone scanning and MRI are useful.

### Management

#### Treatment Approach

For patients without risk factors, treatment of minimally symptomatic or asymptomatic uncomplicated primary *Coccidioides* infections can be deferred provided there is close follow-up. Patients should be assessed periodically for 1 to 2 years to confirm resolution of symptoms and radiographic findings. The IDSA recommends therapy for patients with severe progressive pulmonary disease, for patients at risk for dissemination, and for patients who are experiencing significant morbidity (fever  $>3$  weeks, weight loss  $>10\%$ , persistent large infiltrates, severe malaise, CF titers  $\geq 1:16$ ). Treatment is recommended for all patients with extrapulmonary manifestations of coccidioidomycosis. Surgery may be required for persistent, refractory, localized pulmonary lesions or in cases with bone and joint involvement.

#### Specific Treatments

For patients with mild to moderate acute primary pulmonary infection, oral azoles are the treatment of choice. Duration of treatment needs to be individualized, but may vary from 3 to 6 months. For severe or progressive pulmonary disease, amphotericin B is recommended by the IDSA for initial management until respiratory symptoms resolve. Amphotericin B is also recommended for use in pregnant women, because azoles are potentially teratogenic. Azole antifungals are preferred for initial treatment of patients with CNS and meningeal involvement. For CNS infections refractory to fluconazole, repetitive intrathecal instillation of amphotericin B may be required. Duration of treatment for CNS infection and for HIV-infected patients is lifelong, because of the high risk of disease relapse in these patients.

### When to Admit

All children with severe acute pulmonary infections requiring intravenous therapy and supplemental oxygen, and all children with disseminated infections, especially those involving the CNS or meninges, should be admitted.

### When to Refer

All suspected or proven cases of coccidioidomycosis should be referred to infectious disease specialists. For children with persistent, refractory, localized pulmonary lesions or with bone and joint involvement, surgeons and interventional radiologists should be involved.

### Ongoing Care

#### Follow-Up

Periodic monitoring of symptoms and periodic radiological assessment of patients with primary pulmonary coccidioidomycosis is needed for 1 to 2 years or until disease resolution. For patients with disseminated coccidioidomycosis, CF titers should be monitored every month until titers have dropped to less than 1:8. Relapses of coccidioidomycosis can be

predicted by symptom recurrence, physical findings, and CF titer increases.

### Prognosis

In 90% to 95% of patients with primary coccidioidomycosis, the infection resolves without significant sequelae; the remaining 5% to 10% of patients develop chronic pulmonary or extrapulmonary disease. As discussed before, disseminated coccidioidomycosis is uncommon, typically involves infection of the skin, bone or joints, lymph nodes, or CNS, and is associated with increased morbidity and mortality. Mortality with disseminated infection among immunocompromised individuals can be as high as 70% despite appropriate therapy. Untreated meningitis is fatal in 100% of patients.

### Prevention

Currently no vaccine has been approved for the prevention of *Coccidioides* infection. Vaccine developments for high-risk individuals have been reviewed and appear promising. Primary prophylaxis with an azole is not recommended for HIV-infected individuals. Special measures should be taken in endemic areas to control dust at construction sites. People residing in or traveling to endemic regions should avoid high-risk activities and wear respiratory masks if exposure is unavoidable.

## SPOROTRICHOSIS

### Etiology

Sporotrichosis is a rare fungal infection caused by *Sporothrix schenckii*. *Sporothrix schenckii* is a thermally dimorphic fungus found in a mold or mycelial form at room temperature and as yeast at 37°C in host tissues.

### Epidemiology

Although *S. schenckii* has a global distribution, most cases of sporotrichosis are reported in tropical regions of the Americas. Most cases in North America have been reported in the Midwest. Sporotrichosis can occur in all age groups and has no racial or gender predilection. An increased frequency among men is attributable to occupational exposures. *S. schenckii* may be isolated from plants such as rosebush, barberry, straw, hay, sphagnum moss, and decaying vegetation. Animal-to-human transmission, most notably from cats and armadillos, has occurred.

### Risk Factors

Individuals at increased risk of *S. schenckii* infections include farmers, gardeners, veterinarians, and laboratory workers. Other predisposing conditions for sporotrichosis include diabetes mellitus, alcoholism, and injection drug use. The risk of disseminated sporotrichosis is high among immunocompromised patients, including individuals with HIV infection.

### Dagnosis

#### Signs and Symptoms

Sporotrichosis can manifest as localized or fixed cutaneous, lymphocutaneous, or extracutaneous infection.

**Figure 254-13** *Sporothrix schenckii* was cultured from the biopsy specimen from an abscessed cervical lymph node of this 10-year-old boy. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

Lymphocutaneous sporotrichosis is the most commonly recognized form and accounts for more than 75% of pediatric cases. Lymphocutaneous sporotrichosis presents initially as a painless papule at the site of inoculation. Such lesions are more common on the face and hands and occur more frequently in children. The papule, over a varied period, evolves into a nodular, ulcerated lesion. In approximately 25% of children, *S. schenckii* infection remains as a solitary lesion without lymphatic spread. When lymphatic spread does occur, the infection spreads proximally along the lymphatic distribution of the affected extremity, producing nodular swellings that are often associated with palpable regional lymphadenopathy (Figure 254-13). Multiple disseminated cutaneous lesions are uncommon, but can occur with multiple inoculation sites, usually in immunocompromised individuals.

Pulmonary sporotrichosis follows inhalation of aerosolized spores and manifests as a subacute or chronic pneumonia that mimics tuberculosis. Disseminated sporotrichosis follows hematogenous or lymphatic spread from initial cutaneous or pulmonary infection. The usual organs of dissemination are the skin, joints, eyes, and CNS. Pulmonary and disseminated forms of sporotrichosis are rarely encountered in children.

### Differential Diagnosis

According to the epidemiologic settings and exposures, etiologic considerations include tuberculosis, lupus vulgaris, blastomycosis, chromoblastomycosis, paracoccidioidomycosis, and leishmaniasis. Some cutaneous infections are difficult to distinguish from actinomycosis, nocardiosis, and nontuberculous mycobacterial disease.

**Figure 254-14** *Sporothrix schenckii*, yeast phase; round, oval, and fusiform (cigar-shaped) cells. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

### Laboratory Findings

Definitive diagnosis of *S. schenckii* infection requires isolation of the fungus in culture, or by detection of *S. schenckii* in tissue specimens using periodic acid–Schiff, methenamine silver, or immunohistochemical stains (Figure 254-14). The diagnostic yield of histopathologic specimens is low because of a paucity of organisms in infected tissue. Granulomatous inflammation with occasional asteroid bodies can be seen in histopathologic specimens. Serologic testing and PCR assay have high sensitivity and specificity, but are not available widely.

### Management

Lymphocutaneous sporotrichosis rarely resolves without treatment. The duration of therapy is usually 3 to 6 months. Itraconazole is the drug of choice for cutaneous and lymphocutaneous sporotrichosis and is more effective than fluconazole. For cutaneous and lymphocutaneous infections, a saturated solution of potassium iodide has been used and still is recommended as an alternative treatment option. Amphotericin B, followed by a prolonged course of itraconazole, is used for disseminated sporotrichosis and for severe pulmonary infection. Children with invasive sporotrichosis and HIV coinfection are treated initially with amphotericin B followed by lifelong itraconazole maintenance therapy.

### Ongoing Care

The prognosis of cutaneous and lymphocutaneous sporotrichosis after therapy is excellent. Osteoarticular sporotrichosis may be complicated by chronic osteomyelitis and arthritis with consequent deformity and loss of joint function. Disseminated sporotrichosis carries significant morbidity and mortality in immunocompromised hosts.

## MALASSEZIA

*Malassezia furfur* is a lipophilic, saprophytic, budding, dimorphic, oval-to-round yeast. *M. furfur* is part of the normal skin flora, and causes clinical disease only when there is substantial transformation of yeast to hyphal forms. *Malassezia* species are responsible for superficial skin infections in all age groups. The most common

**Figure 254-15** *Malassezia furfur*. Pneumonitis. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org))

manifestation of cutaneous *Malassezia* infection is pityriasis versicolor. Pityriasis versicolor occurs globally, but is predominantly present in tropical and subtropical regions. Recently, *Malassezia* species have been increasingly recognized as a cause of invasive disease in premature infants and in other immunocompromised hosts who are receiving lipid-supplemented parenteral nutrition.

### Risk Factors

Among both infants and adults, exposure to intravenous lipid infusions through a CVC is the most important risk factor for systemic *Malassezia* infection. Neonates with low birth weight, low gestational age, and prolonged hospitalization are at high risk. Antibacterial therapy has been identified as an additional risk factor for disease.

### Diagnosis

#### Signs and Symptoms

*Malassezia* species can cause various superficial skin infections in humans, including pityriasis versicolor, folliculitis, seborrheic dermatitis, and even atopic dermatitis. Symptoms of catheter-associated fungemia secondary to infection with *Malassezia* species are indistinguishable from those related to other causes, but should be suspected in high-risk neonates with sterile blood cultures. Clinical manifestations of invasive *Malassezia* infection include fever, respiratory distress, apnea, bradycardia, and thrombocytopenia. The heart and lungs are the most commonly affected organs resulting in mycotic thrombi around the tips of catheters; mycotic vegetations on the endocardium and heart valves; vasculitis; and inflammation of alveoli, bronchi, and bronchioles. Usually, no signs of infection and no skin rash are evident at catheter insertion sites.

### Laboratory Findings

Direct microscopic examination of scrapings from skin lesions can reveal clusters of round to oval budding yeast cells and short hyphae (the so-called “spaghetti and meatball” appearance) (Figure 254-15).

Ag, antigen; CNS, central nervous system; DIC, disseminated intravascular coagulation; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; GI, gastrointestinal; GU, genitourinary; HSM, hepatosplenomegaly; PCR, polymerase chain reaction; PNA-FISH, peptide nucleic acid fluorescent in situ hybridization.

<sup>a</sup>See text for indications and duration of treatment.

With the exception of *M pachydermatis*, *Malassezia* do not grow readily on standard mycologic media, and require addition of olive oil to Sabouraud dextrose agar to provide the long-chain fatty acids needed for growth of *Malassezia* species.

### Management

Systemic *Malassezia* infection can be treated successfully with prompt removal of the colonized catheter and discontinuation of the contaminated lipid infusion. In cases of invasive fungemia, amphotericin B or fluconazole may be used. The use of fat emulsions containing medium-chain triglycerides inhibits the growth of *Malassezia* and may prevent infection.

### SUMMARY

Table 254-1 and Table 254-2 provide an overview of systemic fungal infections and antifungal agents.

### Chapter 255

## GASTROESOPHAGEAL REFLUX DISEASE

Jenifer R. Lightdale, MD, MPH

### DEFINITIONS

Gastroesophageal reflux (GER) is a normal physiologic process that entails relaxation of the lower esophageal sphincter independent of swallowing and allows gastric contents to pass into the esophagus. GER occurs transiently several times a day in healthy infants, children, and adults and is generally unaccompanied by symptoms. In contrast, gastroesophageal reflux disease (GERD) is globally defined as troublesome symptoms or complications associated with GER. The symptoms of GERD can be either esophageal or extraesophageal and can be further characterized by findings of mucosal injury on upper endoscopy.

Both GER and GERD can be associated with vomiting, which is defined as a forceful expulsion of gastric contents through a coordinated autonomic and voluntary motor response. Regurgitation occurs when gastric contents enter into the oropharynx. Vomiting and regurgitation can be further differentiated from rumination, in which recently ingested food is effortlessly regurgitated into the mouth, masticated, and reswallowed.

### EPIDEMIOLOGY

GER, as characterized by regurgitation, occurs in more than two-thirds of otherwise healthy infants and has been found to be a voiced topic of parental concern in 20% to 25% of 6-month well-child visits. The terms “spitting-up,” “possetting,” and “spilling” are considered equivalent to regurgitation, which is the most visible symptom of GER in infants. One study reported at least 1 episode of regurgitation per day in 0- to 3-month-olds, with peak-reported regurgitation in two-thirds of infants at 4 months and general resolution by 1 year of age. International reports suggest that infant regurgitation is a global phenomenon that is mainly prevalent in the first 5 months of life and almost always resolves by 12 to 14 months. (see Figure 255-1).

GERD is far less common than GER in pediatric populations, and determining its prevalence, particularly in infants who have variable clinical presentations, may be impossible. One rigorous study in the United Kingdom suggests the incidence per 1,000 person years is 0.84 in children 1 to 18 years of age. Recent studies suggest there is likely a genetic basis for GERD and its complications, including erosive esophagitis, Barrett esophagus, and esophageal carcinoma. Reports have been published of familial clustering of Barrett esophagus, and monozygotic twins have a higher concordance for GERD than dizygotic twins. However, data supporting a specific genetic link are lacking. It is not known whether pediatric symptoms of GERD are a risk factor for complications of GERD later in life. A few pediatric populations have been identified to be at high risk for GERD and its

complications, including children with neurologic impairment, prematurity, and esophageal atresia.

## CLINICAL MANIFESTATIONS

Symptoms, many of which are troublesome, and signs of GERD generally depend on the age of the patient (see Box 255-1). Clinical manifestations may be different as children grow older and with the development of language (see Box 255-2). Common presenting symptoms in infants include refusing to eat or failing to thrive. Infant crying has also been presumed to be a symptom of discomfort from acid reflux, despite the fact that no studies have shown correlation of crying with GER. GERD in infants can also be associated with extraesophageal symptoms of coughing, choking, wheezing, or upper respiratory symptoms. Older children may complain of abdominal pain but may not localize the pain to the epigastrium or retrosternal areas. Adolescents are more likely to report heartburn or chest pain symptoms in a similar manner to adults. Extraesophageal symptoms and signs, such as wheezing, stridor, and dystonic neck posturing, may occur at any age.

## PATHOPHYSIOLOGY

The causes of GER and GERD are multifactorial and depend on anatomy, motility, and pathophysiologic factors. In an infant, the normally obtuse angle of His does not occlude the hiatus when the stomach is distended postprandially and may result in regurgitation. In line with the overall smaller body size, the infant esophagus is relatively short compared with an adult esophagus, and the infant's gastric capacity is less. In turn, gastric contents may more easily move into the esophagus and oropharynx (see Figure 255-2).

**Figure 255-1** Prevalence of gastroesophageal reflux in healthy infants in the first 2 years of life. (From Martin AJ, Pratt NJ, Kennedy D, et al. Natural history and familial relationships of infant spilling to 9 years of age. *Pediatrics*. 2002;109:1061–1067)

In both children and adults, the most common cause of GERD is inappropriate lower esophageal sphincter (LES) relaxation with inhibition of esophageal peristalsis. Transient LES relaxations typically occur up to 5 times in the immediate postprandial hour with episodic movement of gastric contents into the distal esophagus. These relaxations are vagally mediated, are brief in duration, and probably play a normal role in eliminating gas from the stomach. When the refluxate enters the esophagus, it is buffered by saliva and cleared by normal esophageal peristalsis. In patients with GERD, these relaxations last longer, from 5 to 35 seconds. During this period, a combination of LES hypotonia and inhibited esophageal peristalsis prolongs the contact time of the gastric contents with the esophageal mucosa and contributes to tissue injury. Inappropriate LES relaxation and delayed gastric emptying have been shown to occur in 28% to 50% of children with GERD.

Increasing intra-abdominal pressure (crying in infants, coughing, obesity) or gastric acid secretion, as well as consuming large meals, fatty foods, caffeinated

### BOX 255-1 Symptoms and Signs That May Be Associated With Gastroesophageal Reflux

#### SYMPTOMS

- Recurrent regurgitation with/without vomiting
- Weight loss or poor weight gain
- Irritability in infants
- Ruminative behavior
- Heartburn or chest pain
- Hematemesis
- Dysphagia, odynophagia
- Wheezing
- Stridor
- Cough
- Hoarseness

#### SIGNS

- Esophagitis
- Esophageal stricture
- Barrett esophagus
- Laryngeal or pharyngeal inflammation
- Recurrent pneumonia
- Anemia
- Dental erosion
- Feeding refusal
- Dystonic neck posturing (Sandifer syndrome)
- Apnea spells
- Apparent life-threatening events

From Vandenas Y, Rudolph CD, Di Lorenzo C, et al. Pediatric gastroesophageal reflux clinical practice guidelines: joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN). *J Pediatr Gastroenterol Nutr*. 2009;49:498–547. Reproduced with permission from Wolters Kluwer Health, Inc.

beverages, candy, and certain medications (theophylline, morphine, calcium-channel blockers) that lower the LES tone, have also been found to contribute to the presence and severity of GERD. Other risk factors include pathologic conditions such as malrotation, annular pancreas, or antral web. Impaired esophageal motility associated with repair of esophageal atresia or tracheoesophageal fistula or delayed gastric emptying may result in prolonged acid exposure in the

esophagus and eventual complications of GERD. Impaired buffering of acid in the esophagus by saliva may lead to esophagitis in children with cystic fibrosis or adults with autoimmune disease.

### Esophageal Complications

Gastrointestinal (GI) bleeding associated with hematemesis, melena, guaiac-positive stools, or anemia can occur as a complication of GERD resulting from erosive esophagitis. Peptic strictures are a long known complication of severe GERD, especially in patients with neurologic impairment or esophageal motility disorders. Children with peptic stricture may complain of dysphagia or refuse to eat solids. Impaction of food may be the initial presentation. Peptic strictures are readily seen by barium swallow and are usually located in the distal third of the esophagus. Barrett epithelium, which is defined as the replacement of normal stratified esophageal epithelium with columnar epithelium and goblet cells, is highly associated with peptic strictures in adults but is relatively rare in children. Barrett epithelium may be premalignant. Case reports have been issued of children with Barrett epithelium–associated adenocarcinoma, but the prevalence of esophageal cancer in children is extremely rare. Children with Barrett esophagus should be managed in accordance with adult guidelines and undergo appropriate surveillance for dysplasia.

### Extraesophageal Complications

#### *Chronic Cough, Stridor, Hoarseness*

Data linking GERD in children with chronic cough, stridor, and hoarseness are limited to case reports and case series, and controlled studies of the use of acid

### BOX 255-2 Common Presenting Symptoms of Gastroesophageal Reflux Disease in Children

#### INFANTS

- Feeding refusal
- Recurrent vomiting
- Poor weight gain
- Irritability
- Sleep disturbance
- Respiratory symptoms

#### OLDER CHILDREN AND ADOLESCENTS

- Abdominal pain, heartburn
- Recurrent vomiting
- Dysphagia
- Asthma
- Recurrent pneumonia
- Upper airway symptoms (chronic cough, hoarse voice)

From Lightdale JR, Gremse DA; Section on Gastroenterology, Hepatology, and Nutrition. Gastroesophageal reflux: management guidance for the pediatrician. *Pediatrics*. 2013;131:e1684–e1695.

**Figure 255-2** A number of factors contribute to the frequency of regurgitation in infants. A shorter esophagus, the small capacity of the esophagus, and recumbent posture (lack of gravity) make it more likely that refluxed material in the infant will fill the esophagus and pass into the pharynx. The infant is thus more likely to regurgitate than the adult when gastric contents empty into the esophagus. The esophagus is approximately 11 cm at birth, with a diameter of 5 mm. By adulthood, the esophagus is 24 to 30 cm long, with lateral and anteroposterior diameters of 30 and 19 mm, respectively.

suppression to treat these presumed GERD-related symptoms have not shown clinical improvement. Recent guidelines from the North American Society of Pediatric Gastroenterology Hepatology and Nutrition (NASPGHAN) state that patients with these symptoms should not be assumed to have GERD without a comprehensive evaluation for other potential etiologies.

### **Recurrent Pneumonia**

GERD may cause recurrent pneumonia and interstitial lung disease and may occur without esophagitis. Although reflux causing recurrent pneumonia has been reported in otherwise healthy children, those with neurodevelopmental disorders present a special diagnostic problem because oropharyngeal incoordination may result in aspiration without reflux. Aspiration during swallowing in many patients, especially patients with neurodevelopmental disorders, may be more common than aspiration of refluxed material. In turn, diagnosing GERD as a factor in lung disease may be challenging. Although lipid-laden alveolar macrophages have been considered an indicator of aspiration, multiple studies have shown that this finding has poor sensitivity and specificity as an indicator of reflux-related lung disease.

### **Asthma**

Although symptoms of reflux are common in children with asthma, and a high percentage of children with persistent asthma have abnormal pH monitoring results, the relationship between asthma and GERD remains a challenge for the physician. Esophageal acid exposure per se has a minimal effect on pulmonary function but has been shown to contribute to increased airway responsiveness in asthmatic patients. A pathophysiologic explanation for this may lie in the fact that vagal afferents innervate both the esophagus and the bronchi and allow acid stimulation of receptors in the esophagus to induce reflex bronchoconstriction. Alternatively or additionally, micro-aspiration of gastric contents into the trachea may result in bronchoconstriction and laryngospasm.

The prevalence rates of GERD-associated asthma are reported to range from 25% to 75%. Interestingly, approximately 50% of patients with persistent asthma who test positive for GERD by pH monitoring have no or minimal symptoms of GERD. In one arm of a clinical trial of asthmatic children ages 5 to 10 years, children with normal pH monitoring results were randomized to receive a proton pump inhibitor (PPI) or no acid-suppression treatment. Approximately 25% of asthmatic children with normal pH probe studies were able to decrease their asthma medication, whereas children who were not treated with acid-suppression medication continued on the same dose of asthma medication. Studies have shown an improvement of asthma symptoms after a variety of medical therapies for GERD that have included positional therapy, thickening of formula without medication, promotility agents, and treatment with histamine-2 receptor antagonists (H2RAs). Currently, evidence in children is insufficient to establish optimal medical therapy for GER in patients with asthma, and the best diagnostic test to determine whether an association between asthma and GERD

exists remains an empirical trial of a PPI for acid suppression.

### **Apnea or Apparent Life-Threatening Event**

An apparent life-threatening event (ALTE) is an episode occurring in an infant that requires intervention and that is characterized by a combination of apnea, cyanosis, pallor, rubor, plethora, limpness, stiffness, choking, or gagging. (See Chapter 217, Apparent Life-Threatening Events.) To date, evidence to support a clear causal relationship between GERD and ALTE is lacking. Instead, it is recognized that in highly selected cases, reflux may be associated with pathologic, central, and obstructive apnea. Medical therapy of GERD in infants with ALTE should be considered a reasonable therapeutic option to pursue but cannot be considered a reliable means of preventing a subsequent ALTE. The use of surgical therapy for GERD to prevent ALTE remains unproved and should be considered only in infants with ALTE that is unresponsive to acid-suppression therapy and is known to be associated with GERD.

### **Sandifer Syndrome**

Sandifer syndrome is a rare complication of GERD usually seen in otherwise neurologically normal children and characterized by stereotypical, repetitive stretching and arching movements thought to be related to esophageal pain. These behaviors may be mistaken for atypical seizures or dystonia.

### **Dental Erosions**

An emerging association between GERD and dental erosions seems to correlate in severity to exposure of the proximal esophageal or oral cavity to acidic gastric contents. Young children and those with neurologic conditions may be at greatest risk. Beyond GERD, other contributing factors to dental erosions that can be considered either causal or additive include juice drinking, bulimia, and genetic factors that affect the characteristics of the enamel and saliva.

## **EVALUATION**

There is no single gold standard test or testing approach that allows a definitive diagnosis of GER or GERD. Instead, the diagnosis of reflux disorders is generally made on the basis of a description of symptoms in the absence of alternative diagnoses. To this end, there are a myriad of diagnostic modalities that can be used in a thoughtful and serial manner to provide specific information about the cause and severity of acid reflux and to investigate for associated or alternative conditions.

### **History and Physical Examination**

In most infants with vomiting, and in older children with regurgitation and heartburn, a history and physical examination are sufficient to reliably diagnose uncomplicated GER and GERD, recognize complications, and initiate treatment strategies (see Box 255-3 and Box 255-4). Obtaining a dedicated clinical history and performing a physical examination are also critical to excluding more worrisome diagnoses that can

### BOX 255-3 History in the Child With Suspected Gastroesophageal Reflux Disease

#### FEEDING HISTORY

- Amount/frequency (overfeeding)
- Primary source of dietary proteins
- Preparation of formula
- Recent changes in feeding type or technique
- Position during feeding
- Burping
- Behavior during feedings (choking, gagging, coughing, arching, discomfort, refusal)

#### PATTERN OF VOMITING

- Amount/frequency
- Pain
- Forceful
- Blood or bile
- Associated symptoms (constipation, fever, lethargy, diarrhea)
- Associated pattern of stooling

#### MEDICAL HISTORY

- Stool frequency and consistency
- Prematurity
- Growth and development
- Past surgery, hospitalizations
- Newborn screen results
- Recurrent illness (croup, pneumonia, reactive airways)
- Apnea
- Previous weight and height gain
- Warning signals (see Box 255-4)
- Other chronic conditions

#### MEDICATIONS

- Current, recent, prescription, nonprescription

#### FAMILY PSYCHOSOCIAL HISTORY

- Sources of stress
- Parental drug use
- Postpartum depression

#### FAMILY MEDICAL HISTORY

- Significant illness
- Family history of gastrointestinal disorders
- Family history of atopy

#### GROWTH CHART

- Length, weight, head circumference
- Weight-for-length, body mass index

present with reflux, vomiting, and other symptoms associated with reflux disorders (see Box 255-5).

### Differential Diagnosis

A variety of conditions have clinical features that resemble GER, including eosinophilic esophagitis, food allergy, achalasia, cyclic vomiting syndrome, pill esophagitis, infectious esophagitis, and rumination syndrome. These conditions may be suspected based on characteristic features in combination with diagnostic testing. A failure of symptoms to respond to standard medical therapy for acid reflux may also be an indication to investigate for alternative diagnoses.

### Eosinophilic Esophagitis

Eosinophilic esophagitis occurs in young children, teenagers, and adults. Younger children may have symptoms suggestive of GERD such as abdominal pain or food refusal. Dysphagia or esophageal food impaction is more commonly noted in older children. A personal or family history of allergic disease can be found in 75% of cases. The diagnosis is suspected when white exudate, circular rings, or linear furrowing is seen during upper endoscopy. Establishing the diagnosis depends on finding more than 15 eosinophils per high-power field on an esophageal mucosal biopsy.

### Food Allergy

Infants with intolerance to cow's milk protein have been shown to experience regurgitation and vomiting indistinguishable from that associated with physiologic GER. Generally speaking, cow's milk protein is

Reproduced with permission from Wolters Kluwer Health, Inc.

among the first and most common proteins in an infant's diet and accordingly is one of the most common causes of food allergy. The prevalence of infant sensitivity to intact milk and other protein in the diet has been reported to be as high as 17% in developed countries. Such sensitivities vary in severity of reactions, are most often related to non-immunoglobulin E mediated allergy, and may be temporally dissociated from ingestion and feeding times. Similarly, although there are no studies specifically evaluating soy protein allergy, intact soy protein may also be associated with formula intolerance and vomiting. In turn, several well-controlled rigorous trials lend strong support for the use of hypoallergenic (extensively hydrolyzed or amino acid-based) formulas in formula-fed infants as well as withdrawal of cow's milk and eggs from the maternal diet in breast-fed infants. Recent evidence has implicated vitamin D deficiency as a potential modifiable risk factor for food allergy, but guidelines

around prevention and treatment in this respect have not been developed.

**Achalasia**

Achalasia is a neurodegenerative motor disorder characterized by a lack of peristalsis in the distal two-thirds of the esophagus, an elevated resting pressure in the distal esophagus, and failure of the LES to relax. The result is a functional obstruction in the lower esophagus and accumulation of food in the esophagus. This condition is extremely rare in childhood, with an incidence of 0.11 per 10,000 children annually. Children may exhibit weight loss, regurgitation of undigested food, halitosis, cough (especially when supine), or pneumonia. The most common feature on chest radiograph is an absence of air in the stomach and an air-fluid level in the esophagus. A barium esophagram often reveals a symmetrical narrowing in the distal esophagus with the appearance of a bird

beak. However, in young children with achalasia, sphincter relaxation and occasional peristalsis may be present. Esophageal manometry is often diagnostic.

### **Cyclic Vomiting Syndrome**

Cyclic vomiting syndrome is a functional, debilitating GI disorder of childhood characterized by bouts of intractable nausea and vomiting lasting for hours, accompanied by lethargy and pallor and interspersed with complete symptom relief. Reported incidence rates range from 1.7% to 2.7% of school-aged children, and the disorder has been reported in a number of countries around the world. The exact pathogenesis of cyclic vomiting syndrome remains unknown, but it has been well linked to migraine and is considered centrally mediated. During episodes, children may require hospitalization and supportive care. Although these episodes are intense in severity, in contrast to GERD, the child is completely asymptomatic between episodes. Bouts of vomiting may be triggered spontaneously, by stress, or by menstruation, and there is often a strong family history of migraine. No diagnostic test or identifiable neurologic, metabolic, or other GI disease exists to explain the condition, but recent guidelines on cyclic vomiting syndrome have been issued from both NASPGHAN and its European counterpart society to clarify the diagnostic process. Both guidelines emphasize the importance of excluding other possible conditions, including identifiable metabolic diseases, obstructive uropathy, and intracranial processes, before diagnosing cyclic vomiting syndrome.

### **Pill Esophagitis**

Pill esophagitis occurs when a pill becomes lodged in the esophagus; it is characterized by an acute onset of severe midchest or substernal pain and dysphagia. Both antibiotic treatments for acne (eg, doxycycline, minocycline) and nonsteroidal anti-inflammatory medications (eg, ibuprofen), especially in adolescents who may swallow medications without adequate liquids, have been well described as culprits in this scenario. The condition should be suspected based on history, and endoscopy may not be necessary if symptoms improve with acid-suppression therapy or sucralfate.

### **Infectious Esophagitis**

Most infectious causes of esophagitis present with odynophagia and not dysphagia. Herpes simplex virus, cytomegalovirus, and fungal infections such as candidiasis may occur in both immunocompetent and immunocompromised hosts. Upper endoscopy may be beneficial in making the diagnosis both by histopathology and by culture.

### **Rumination Syndrome**

Rumination syndrome is characterized by the regurgitation of food into the mouth with subsequent reswallowing of the material. Repeated masticatory movements, swallowing air, and tensing abdominal musculature help distinguish rumination from effortless GERD. Rumination syndrome was previously thought to occur in neurologically compromised children but is now recognized as occurring in otherwise healthy

children and adolescents. It may also be a sign of underlying psychological distress or psychiatric disorders, and its treatment generally involves professional counseling and occasionally psychiatric medications.

### **Diagnostic Procedures**

Testing to definitively diagnose reflux disorders does not exist. Instead, thoughtful and serial diagnostic procedures should document the presence of reflux or gastric contents in the esophagus, detect complications, establish a causal relationship between reflux and symptoms, evaluate the efficacy of therapies, and exclude other conditions.

### **Esophageal pH and Impedance Monitoring**

Esophageal pH with impedance monitoring represents tools that can be used independently or in combination to quantify both acid and nonacid refluxate in the esophagus. Esophageal pH is evaluated using a transnasally placed probe that records the number and duration of acid reflux episodes. Multiple intraluminal electrical impedance measures changes in electrical resistance and conductance in the mucosa when a fluid bolus moves down the esophagus, and this resistance and conductance detects nonacid and acid reflux.

Generally speaking, both esophageal pH and impedance monitoring should be performed for a clinically meaningful period of time (ie, 12 to 24 hours) with recording, allowing the physician afterward to determine the frequency and duration of reflux as well as its pH. The percentage of total time during which the esophageal pH is less than 4, referred to as *reflux index*, is considered the most valid measure of reflux. A reflux index of 12% or greater in infants younger than 1 year and 6% or greater in children older than 1 year is considered abnormal. It has been reported that up to 95% of children with mucosal evidence of esophagitis have an abnormal reflux index. On the other hand, only 50% of children with a positive pH study have esophagitis, and the severity of esophagitis has not been found to correlate with the reflux index.

Mounting evidence over the past decade has suggested that independent esophageal pH monitoring is of limited value in evaluating pediatric reflux disorders and that combined pH and multiple intraluminal impedance testing should be considered the standard. Nevertheless, combined pH and multiple intraluminal impedance testing is best recognized as a means of detecting temporal relationships between specific clinical symptoms and acid reflux, rather than an independent means of diagnosing GERD.

### **Endoscopy and Esophageal Biopsy**

The performance of upper endoscopy allows for the direct visualization of the esophageal mucosa to determine the presence and severity of injury from the reflux of gastric contents into the esophagus. Esophageal biopsies should be obtained to allow for the evaluation of the microscopic anatomy. Upper endoscopy with esophageal biopsy is useful to evaluate inflammation in the esophageal mucosa from GERD and to exclude other associated conditions with symptoms that can mimic GERD such as eosinophilic esophagitis.

However, the diagnostic benefits of upper endoscopy and esophageal biopsy must be weighed against the minimal, but not negligible, procedural and sedation risks that have been well associated with its performance.

Endoscopy with esophageal biopsies may be indicated in children with suspected GERD who fail to respond to pharmacologic therapy, or as part of the initial management if symptoms of poor weight gain, unexplained anemia or fecal occult blood, recurrent pneumonia, or hematemesis exist. It may also be helpful in the assessment of other causes of abdominal pain and vomiting in children, such as esophageal or antral webs, Crohn esophagitis, peptic ulcer, *Helicobacter pylori* infection, and infectious esophagitis.

Erosive esophagitis is reported less often in infants and children with GERD than in adults with GERD. However, a normal endoscopic appearance of the esophageal mucosa in pediatric patients does not exclude histologic evidence of reflux esophagitis. In turn, the true value of esophageal biopsy is to evaluate for conditions that may mimic the symptoms of GERD, such as eosinophilic esophagitis, infectious esophagitis, Crohn disease, or Barrett esophagus. The NASPGHAN guidelines strongly recommend endoscopy and esophageal biopsy when indicated for the evaluation of GERD in children.

### Scintigraphy

Scintigraphy involves the oral intake of radiolabeled technetium-containing liquid (formula or juice) or solid (often scrambled eggs) followed by scanning the esophagus, stomach, and lungs to detect radiolabeled colloid that has been refluxed or aspirated. In addition, the gastric emptying time may be calculated; it provides additional information for potential therapeutic intervention. Because the techniques of performing scintigraphy are not standardized and age-specific normative data are not available, its role in evaluating GERD in children remains unclear. The NASPGHAN guidelines do not recommend its routine use in the evaluation of children with reflux disorders.

### Upper Gastrointestinal Radiography

Upper GI contrast radiography generally involves obtaining a series of fluoroscopic images of swallowed barium until the ligament of Treitz is visualized, and it should be used for the purpose of delineating anatomy. Upper GI radiographic images should not be obtained to evaluate GI function or to diagnose GER or GERD because they are too brief in duration to adequately rule out the occurrence of pathologic reflux, whereas the high frequency of nonpathologic reflux during the examination can encourage false-positive diagnoses. The observation of the reflux of a barium column into the esophagus during GI contrast studies does not correlate with the severity of GERD or the degree of esophageal mucosal inflammation in patients with reflux esophagitis.

An upper GI series can be useful in the evaluation of vomiting to screen for possible anatomic abnormalities of the upper GI tract but should be recognized as involving radiation exposure. Radiation-sparing imaging may therefore be preferable. For example, in infants with bilious vomiting, an upper GI may be

useful for evaluating for possible malrotation or duodenal web. However, if persistent nonbilious vomiting in an infant has led to a suspicion of pyloric stenosis, pyloric ultrasound should be performed first and upper GI reserved for those situations in which the results of the pyloric ultrasound are equivocal.

## MANAGEMENT

Best practices regarding the management of reflux disorders in infants and children begin with an emphasis on lifestyle changes. For children who require medication, options include buffering agents, acid secretion suppressants, and promoters of gastric emptying and motility. Surgical approaches should be reserved for children who are at risk for life-threatening complications of GERD.

### Lifestyle Changes in Infants

Lifestyle changes to treat GERD in infants may involve a combination of feeding changes and positioning therapy. Modifying maternal diet, changing formulas, and reducing the feeding volume while increasing the frequency of feeds may be effective strategies to address GERD in many children. In particular, the NASPGHAN guidelines emphasize that milk protein allergy can cause a clinical presentation that mimics GERD in infants. Therefore a 2- to 4-week trial of extensively hydrolyzed protein or amino acid-based formula is recommended in formula-fed infants with GERD symptoms, and a maternal elimination diet is recommended in breastfed infants. Several studies have found that breastfed infants may benefit from a maternal diet that restricts cow's milk and eggs.

In one study of formula-fed infants, GERD symptoms resolved in 24% of infants after a 2-week trial of changing to a protein hydrolysate formula thickened with 1 tablespoon of rice cereal per ounce, limiting the volume of feeding to 120 kcal/kg per day, avoiding seated and supine positions, and avoiding environmental tobacco smoke.

Another feeding management strategy involves the use of thickened feeds—either by adding up to 1 tablespoon of dry rice cereal per 1 oz of formula or changing to commercially thickened (added rice) formulas for infants who are not cow milk protein intolerant—that is, recognized in the NASPGHAN guidelines as a reasonable management strategy for infants with both GER and GERD.

Lifestyle changes that may benefit infants with GERD include keeping them in a completely upright position or even placing them prone. A number of recent studies that use impedance and pH monitoring have confirmed older studies that used pH monitoring to demonstrate significantly less gastroesophageal reflux in infants in the flat prone position compared with the flat supine position. However, the guidelines are unequivocal that the risk for sudden infant death syndrome (see Chapter 337, Sudden Unexpected Infant Death) in sleeping infants outweighs the benefits of the prone positioning in the management of GERD and therefore prone positioning should only be considered acceptable if the infant is observed and awake. Prone positioning is suggested to be beneficial in children older than 1 year with either GER or GERD because the risk for SIDS is greatly decreased in older

age groups. Semi-supine positioning, particularly in an infant carrier or car seat, may exacerbate GER and should be avoided when possible, especially after feeding.

### **Lifestyle Changes in Children and Adolescents**

Lifestyle changes that may benefit GERD in older children and adolescents are more akin to recommendations made for adult patients, including the importance of weight loss in overweight patients, cessation of smoking, and avoiding alcohol use. Recommendations for conservatively managing GERD in older children and adolescents again may involve dietary modification and positioning changes, such as elevating the head of the bed, although the effectiveness of the latter as a treatment for GERD in older children has not been as well studied as in infants. In terms of dietary changes, older children and adolescents are advised to avoid caffeine, chocolate, alcohol, and spicy foods as potential symptom triggers. The NASPGHAN guidelines also point out that three independent studies have demonstrated decreased reflux episodes with postprandial chewing of sugarless gum.

### **Pharmacotherapeutic Agents for Pediatric Gastroesophageal Reflux Disease**

Several different medications may be used to treat GERD in infants and children. The 2 major classes of pharmacologic agents for treating GERD are acid suppressants and prokinetic agents. In addition to growing evidence that demonstrates the former to be more effective than the latter, withdrawal of cisapride from commercial availability in most countries, including the United States, has led to a disproportionate use of acid suppressants to manage children with GERD.

#### **Acid Suppressants**

The main classes of acid suppressants are antacids, H2RAs, and PPIs. The principles of using these medications in the treatment of pediatric GERD are similar to those in adults, other than the need to prescribe weight-adjusted doses and the need to consider the form of the drug prescribed (ie, for ease of ingestion in infants and children). Dosage ranges for drugs commonly prescribed for pediatric GERD are listed in Table 255-1.

#### **Antacids**

Antacids are a class of medications that can be used to directly buffer gastric acid in the esophagus or stomach to reduce heartburn and ideally allow mucosal healing of esophagitis. There is limited historical evidence that the on-demand use of antacids can lead to symptom relief in infants and children. Although antacids are generally seen as a relatively benign approach to treating pediatric GERD, it is important to recognize that they are not entirely without risk. Indeed, several studies link aluminum-containing preparations with aluminum toxicity and its complications in children. Similarly, milk-alkali syndrome, a triad of hypercalcemia, alkalosis, and renal failure, has been described in children receiving calcium-containing preparations and adds to the need for caution. According to the NASPGHAN guidelines, chronic

antacid therapy is generally not recommended for the treatment of GERD in children. In addition, the safety and efficacy of surface protective agents, such as alginates or sucralfate, an aluminum-containing preparation, have not been adequately studied in children. As such, no surface agent is currently recommended as independent treatment for severe symptoms of GERD or erosive esophagitis in children.

#### **Histamine-2 Receptor Antagonists**

H2RAs represent a major class of medications that has completely revolutionized the treatment of GERD in children. H2RAs decrease the secretion of acid by inhibiting the histamine-2 receptor on the gastric parietal cell. Expert opinion suggests little clinical difference between the various formulations of H2RAs. Randomized placebo-controlled clinical trials in children have shown that cimetidine and nizatidine are superior to placebo for the treatment of erosive esophagitis in children. Pharmacokinetic studies in school-aged children suggest that gastric pH begins to increase within 30 minutes of the administration of an H2RA and reaches peak plasma concentrations 2.5 hours after dosing. The acid-inhibiting effects of H2RAs last for approximately 6 hours, so H2RAs are quite effective if administered 2 or 3 times a day.

H2RAs have some inherent limitations, however. In particular, a fairly rapid tachyphylaxis can develop within 6 weeks of the initiation of treatment, limiting its potential for long-term use. In addition, H2RAs have been shown to be less effective than PPIs in symptom relief and healing rates of erosive esophagitis. Although most of these downsides have been demonstrated most clearly in adults, they are also thought to affect children. It is also important to recognize that cimetidine has specifically been linked to an increased risk for liver disease and gynecomastia and that these associations may be generalizable to other H2RAs.

#### **Proton Pump Inhibitors**

Most recently, PPIs have emerged as the most potent class of acid suppressants by repeatedly demonstrating superior efficacy compared with H2RAs. PPIs decrease acid secretion by inhibiting H<sup>+</sup>/K<sup>+</sup>-ATPase in the gastric parietal cell canaliculus. PPIs are uniquely able to inhibit meal-induced acid secretion and have a capacity to maintain gastric pH >4 for a longer period of time than H2RAs. These properties contribute to higher and faster healing rates for erosive esophagitis with PPI therapy compared with H2RA therapy. Finally, unlike H2RAs, the acid suppression ability of PPIs has not been observed to diminish with chronic use.

The timing of dosing most PPIs is important for maximum efficacy. Both pediatricians and subspecialists must be diligent at educating their patients to administer PPIs ideally about 30 minutes before meals. All physicians should also recognize that the metabolism of PPIs is known to differ in children compared with adults, with a trend toward a shorter half-life, necessitating a higher dose per kilogram to achieve a similar peak serum concentration and area under the curve. A fairly wide range of effective doses is evident in children. For example, an open-label study of omeprazole in children revealed that an effective

**Table 255-1** Pediatric Doses of Common Medications Prescribed for Gastroesophageal Reflux Disease

MEDICATIONS	DOSES	FORMULATIONS	FDA INDICATED AGES
Cimetidine	30–40 mg/kg/day, divided in 4 doses	Syrup	≥16 yr
Ranitidine	5–10 mg/kg/day, divided in 2 to 3 doses	Peppermint-flavored syrup Effervescent tablet	1 mo–16 yr
Famotidine	1 mg/kg/day, divided in 2 doses	Cherry-banana-mint flavored oral suspension	1–16 yr
Nizatidine	10 mg/kg/day, divided in 2 doses	Bubblegum-flavored solution	≥12 yr
Omeprazole	1–3 mg/kg/day (can be single dose or divided in 2 doses). Should be administered 30 min before eating or on an empty stomach	Sprinkle contents of capsule onto soft foods	2–16 yr
Lansoprazole	1–3 mg/kg/day (can be single dose or divided in 2 doses). Should be administered 30 min before eating or on an empty stomach	Sprinkle contents of capsule onto soft foods or select juices Administer capsule contents in juice through nasogastric tube Strawberry-flavored disintegrating tablet Orally disintegrating tablet via oral syringe or nasogastric tube (≥8 French)	1–17 yr
Esomeprazole	Variable by age from 1 mo to >12 yr	Sprinkle contents of capsule onto soft foods Administer capsule contents in juice through nasogastric tube	1–17 yr
Rabeprazole	20 mg daily	Oral tablet	12–17 yr
Dexlansoprazole	30–60 mg daily	Oral tablet	No pediatric indication
Pantoprazole	40 mg daily (adult dose)	Oral tablet	No pediatric indication

dosage range was 0.7 to 3.3 mg/kg daily, based on improvement in clinical symptoms and the results of esophageal pH monitoring. Lansoprazole 0.7 to 3 mg/kg daily improved GERD symptoms and healed all cases of erosive esophagitis in the treatment of 1- to 12-year-old children with GERD. Other trials of PPI therapy support the efficacy of treatment for severe esophagitis and esophagitis refractory to H<sub>2</sub>RAs in children.

As in adults, PPIs are considered safe and generally well tolerated with relatively few side effects. In terms of their long-term use, published studies have reported PPI use for up to 11 years in small numbers of children. The US Food and Drug Administration has approved a number of PPIs for use in children in recent years, including omeprazole, lansoprazole, and esomeprazole for children 1 year and older and rabeprazole for children 12 years and older. Nonetheless, the new guidelines strike a note of caution when they also discuss reports describing a dramatic rise in past years in the number of PPI prescriptions written for children, particularly infants who may be at increased risk for lower respiratory tract infections.

The overuse or misuse of PPIs in infants with reflux is a matter for great concern. Placebo-controlled trials in infants have not demonstrated superiority of PPIs over placebo for reduction in irritability. Headaches, diarrhea, constipation, and nausea have been described

as occurring in up to 14% of older children and adults prescribed PPIs. Although considered a benign histologic change, enterochromaffin cell hyperplasia has recently been demonstrated in up to 50% of children receiving PPIs for more than 2½ years. Finally, a growing body of evidence suggests that acid suppression in general with either H<sub>2</sub>RAs or PPIs may be a risk factor for pediatric community-acquired pneumonia, gastroenteritis, candidemia, and necrotizing enterocolitis in preterm infants.

### Prokinetic Agents

The desired pharmacologic effects of prokinetic agents include improving the contractility of the body of the esophagus, increasing lower esophageal sphincter pressure, and increasing the rate of gastric emptying. To date, efforts to design a prokinetic agent with benefits that outweigh deleterious side effects have proved difficult. Even metoclopramide, the most common prokinetic agent still available, recently received a Black Box warning regarding adverse side effects, which have been reported in 11% to 34% of patients, including drowsiness, restlessness, and extrapyramidal reactions. Although a meta-analysis of 7 randomized controlled trials of metoclopramide in patients younger than 2 years with GERD confirmed a decrease in GERD symptoms, it was clearly at the cost of such significant side effects. Other drugs in this category

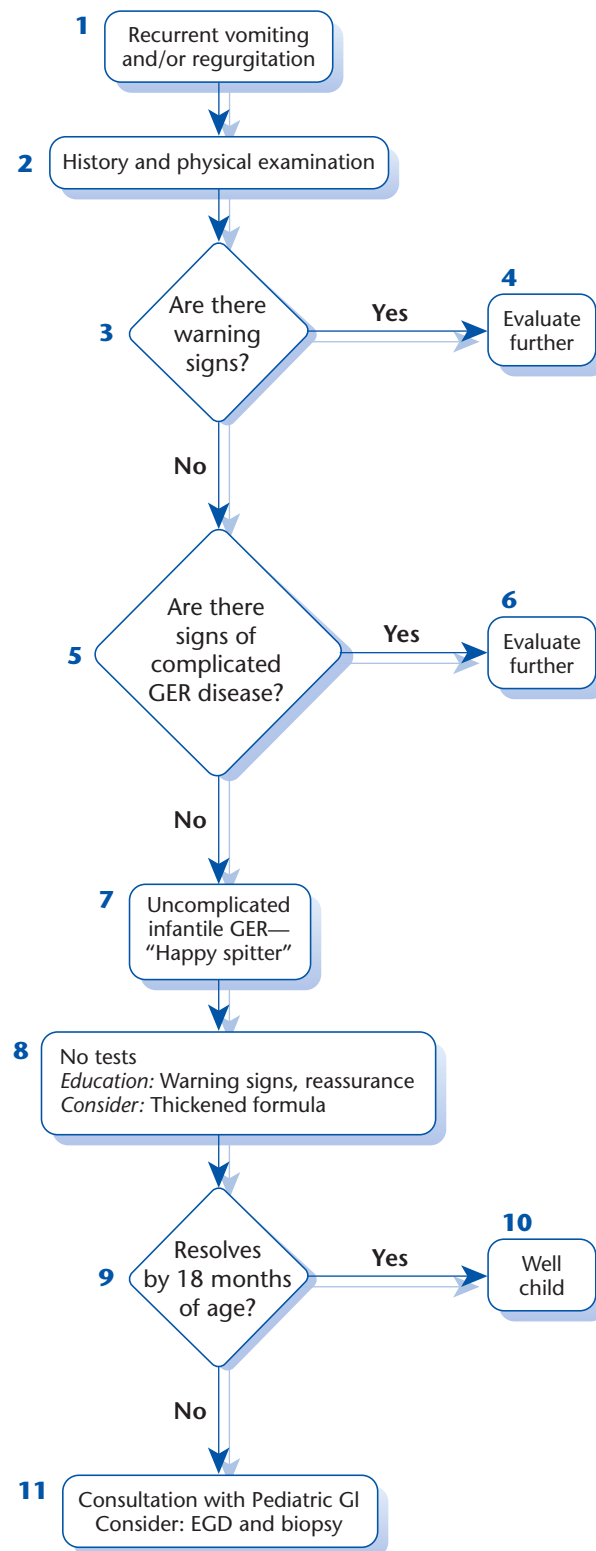

include bethanechol, cisapride, baclofen, and erythromycin. Each works as a prokinetic by using a different mechanism. Nevertheless, after careful review, the NASPGHAN guidelines unequivocally state that there is insufficient evidence to support the routine use of any prokinetic agent for the treatment of GERD in infants or older children.

### Surgery as a Management Strategy in Gastroesophageal Reflux Disease

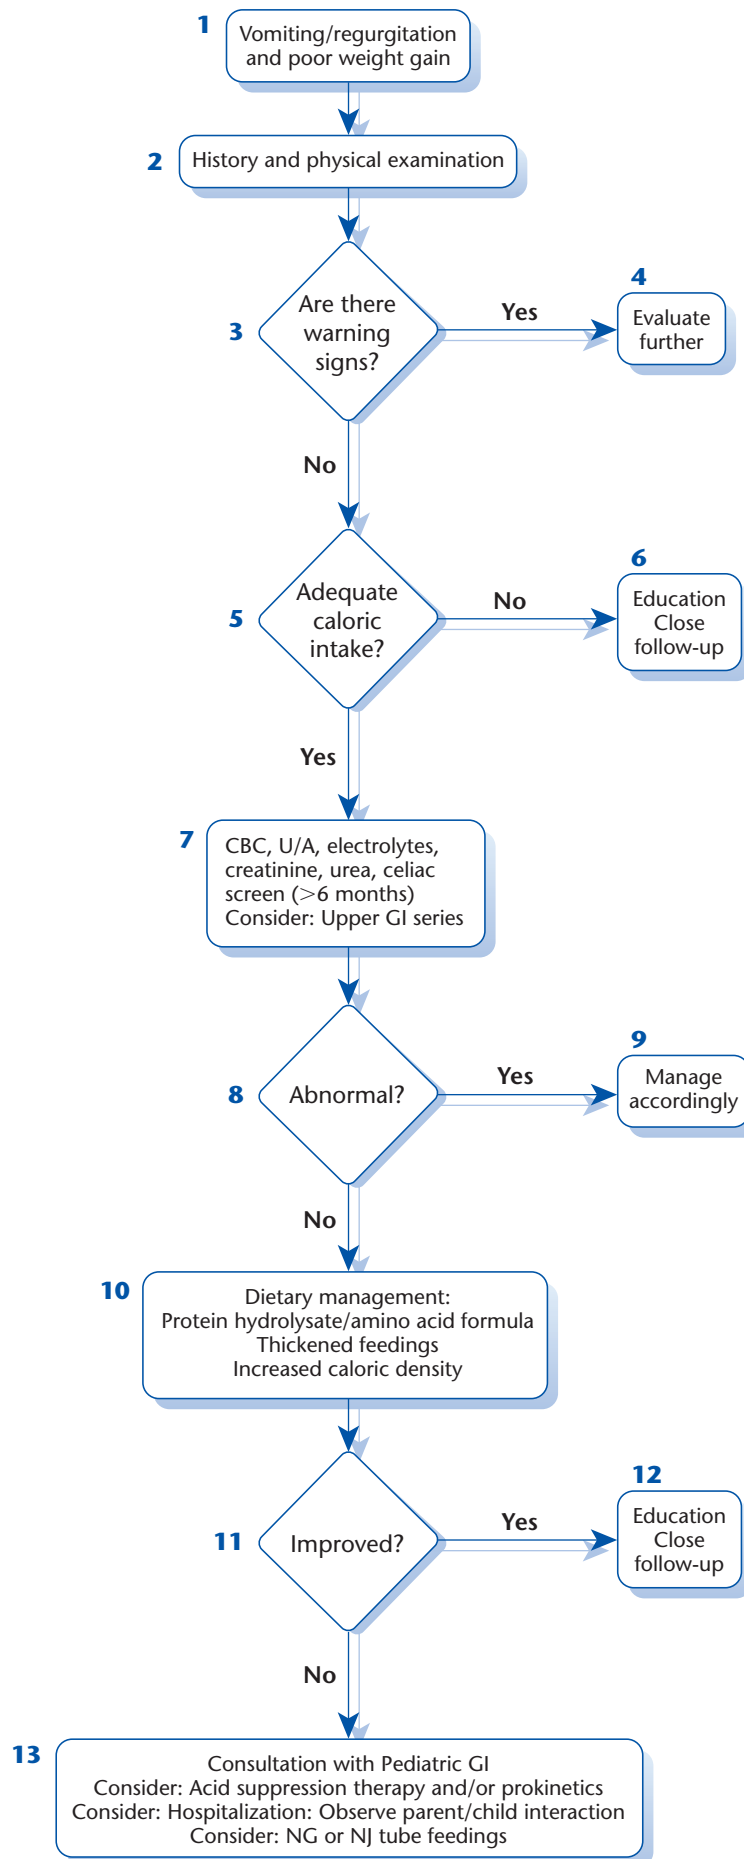

Several surgical procedures can be used to decrease gastroesophageal reflux disorders in children. Fundoplication, whereby the gastric fundus is wrapped around the distal esophagus, is most common and can prevent reflux by increasing the baseline pressure of the lower esophageal sphincter, decreasing the number of transient lower esophageal sphincter relaxations, and increasing the length of the esophagus that is intra-abdominal to accentuate the angle of His and reduce a hiatal hernia, if indicated. Total esophagogastric dissociation is another operative procedure that is rarely used after failed fundoplication. Both procedures carry significant morbidity and do not reduce the risk for the direct aspiration of oral contents. Careful patient selection is one of the keys to successful outcome. Children who have failed pharmacologic treatment may be candidates for surgical therapy, as are children at direct life-threatening risk for aspiration of their gastric contents. In most patients, if acid suppression with PPIs is ineffective, the accuracy of the diagnosis of GERD should be reassessed because fundoplication may not produce optimal clinical results. Clinical conditions such as cyclic vomiting, rumination, gastroparesis, and eosinophilic esophagitis should be carefully ruled out before surgery because they are likely to still cause symptoms after surgery. If anti-reflux surgery is pursued, the NASPGHAN guidelines also stress the importance of providing families with adequate counseling and education before the procedure so that they have a “realistic understanding of the potential complications . . . including symptom recurrence.”

### SUMMARY

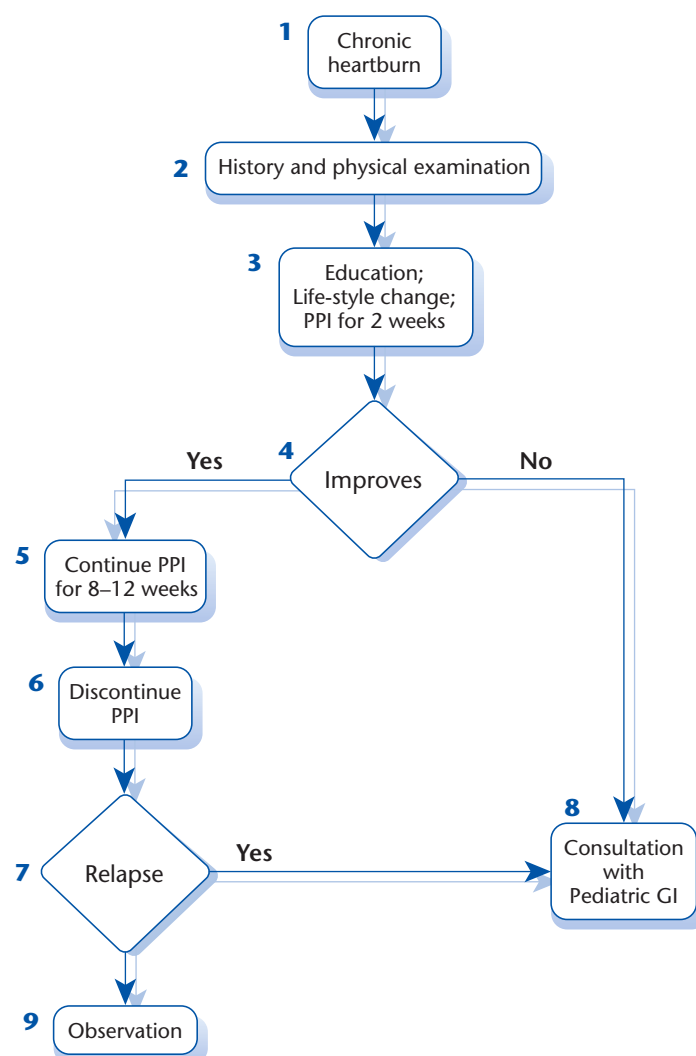

Reflux disorders affect all pediatric age groups. Using an evidenced-based, best practice approach to both testing and managing reflux in infants and children depends on distinguishing GERD from numerous other disorders. In the infant with uncomplicated recurrent regurgitation, it may be important to recognize physiologic GER that is effortless, painless, and not affecting growth (see Figure 255-3). In this situation, physicians should focus on minimal testing and conservative management that emphasizes lifestyle changes and avoids overuse of medications. Physicians must also be able to recognize infants with recurrent regurgitation and troublesome symptoms of GERD (see Figure 255-4). Weight loss or poor growth in infants may be a crucial warning sign that should alter clinical management. Older children with heartburn may benefit from empirical treatment with PPI (see Figure 255-5).

## Chapter 256

# GASTROINTESTINAL ALLERGY

Minou Le-Carlson, MD; John A. Kerner Jr, MD

## INTRODUCTION

Food allergy is a common but often unsubstantiated diagnosis in pediatric practice. An adverse reaction to a food is any untoward reaction regardless of its cause. Such reactions can be classified under 2 general categories: food allergy or hypersensitivity, an immunologic response; and food intolerance, a nonimmunologic response.

## DEFINITIONS

### Food Allergy

The gastrointestinal (GI) tract contains lymphoid tissue capable of mounting an immunologic response to prevent the penetration of antigens across the epithelium. Lymphocytes and plasma cells, including those containing immunoglobulin A (IgA), are present in Peyer patches and the lamina propria of the small and large intestine. The aberrations in immunologic mechanisms that trigger GI allergic reactions are incompletely understood.

The subsequent immunologic response to antigen can be in the form of an immunoglobulin E (IgE)-mediated (immediate GI hypersensitivity and oral allergy syndrome), non-IgE/T-cell-mediated syndrome, or *mixed* GI reaction allergy syndromes. Non-IgE-mediated or T-cell-mediated allergic GI disorders include dietary protein enteropathy, protein-induced enterocolitis, and proctitis. Mixed GI allergy syndromes include eosinophilic esophagitis and eosinophilic gastroenteritis. All of these conditions share a common denominator: the response of the immune system to a specific protein, leading to pathologic inflammatory changes in the GI tract.

GI food allergy can be further divided into 2 types: that involving a specific allergy (a self-limited, mainly T-cell-mediated condition in younger patients that resolves in most by the toddler age), and that characterized by eosinophilic or allergic GI disease with multiple food sensitivities (a more permanent condition caused by a combination of immediate hypersensitivity and non-IgE mechanisms).

Foods that account for 90% of allergic reactions in children are cow's milk protein, eggs, peanuts, soy, tree nuts, wheat, and fish, including shellfish. Food allergies are much more common in infants than in older children because infants may be predisposed to protein allergy caused by enzymatic immaturity, increased gut permeability, and relatively low secretory IgA. Cow's milk protein allergy (CMPA) and soy protein allergy are the most clearly defined allergies in infants.

### Food Intolerance

Meanwhile, food intolerances, unlike food allergies, are non-immune mediated processes. Food intolerance

can occur because of an underlying congenital or acquired enzyme deficiency (eg, disaccharidase deficiency, galactosemia, hereditary fructose intolerance) in which a specific dietary nutrient cannot be metabolized properly; ingestion of a toxin in the food (*Staphylococcus*, shellfish, mushrooms); or ingestion of a pharmacologic agent (metabisulfite in wine or salad may cause bronchospasm, wine and monosodium glutamate may cause headache, and caffeine may cause arrhythmia).

## FOOD ALLERGY

### Clinical Manifestations

#### Cow's Milk Protein Allergy

$\beta$ -Lactoglobulin, the main whey protein, seems to be the most antigenic component of cow's milk, but some infants can be sensitive to casein or whey protein. Early studies showed that the incidence of CMPA was between 0.5% and 7% of all infants under the age of 6 months. Later studies suggested that 2.5% of newborns will have hypersensitivity to cow's milk in the first year of life. Rarely do infants develop CMPA after the first year of age. Previously, physicians counseled families that infants with CMPA would outgrow it by 2 years of age. Later studies revealed that allergy may persist in 72% at age 2, 44% at age 4, and 32% at age 6. Other studies are less pessimistic, finding 44% with persistent symptoms at 1 year, 33% at 2 years, and 23% at 3 years. Patients who have longer persistence of symptoms have a higher frequency of allergic disease and multiple food allergies, and develop symptoms later after initial introduction of milk.

The symptoms and signs of CMPA are listed in Box 256-1. GI symptoms predominate in many patients.

### BOX 256-1 Clinical Manifestations of Cow's Milk Protein Allergy

#### SYSTEMIC MANIFESTATIONS

- Anaphylaxis
- Iron-deficiency anemia (caused by gastrointestinal blood loss)
- Atopic dermatitis, urticaria
- Peripheral eosinophilia
- Poor sleep

#### RESPIRATORY MANIFESTATIONS

- Rhinitis
- Wheezing
- Pulmonary hemosiderosis
- Nasopharyngeal obstruction leading to cor pulmonale

#### GASTROINTESTINAL (GI) MANIFESTATIONS

- Vomiting or gastroesophageal reflux
- Diarrhea, malabsorption, protein-losing enteropathy
- Enterocolitis
- Constipation
- GI bleeding
- Failure to thrive

In other patients, anaphylaxis or pulmonary symptoms occur. Infants with severe atopic dermatitis should also be evaluated for possible CMPA and other food allergy.

The GI manifestations of CMPA depend on the site of predominant inflammation in the GI tract. Esophagitis causes recurrent vomiting and reflux; gastritis causes vomiting, irritability, pain, and occult GI bleeding; enteritis causes diarrhea, malabsorption, or protein-losing enteropathy; and colitis causes rectal bleeding with blood or mucus in the stool.

Although CMPA is more typically associated with colitis symptoms, other symptoms, including gastroesophageal reflux and cow's milk allergic esophagitis, are now well described. Food allergy or formula sensitivity should always be considered in patients with refractory reflux because these 2 conditions may coexist. Antral gastritis is a common finding in these patients, with increased eosinophils and inflammatory cells in the antrum. Duodenal biopsy specimens reveal patchy changes, ranging from normal mucosa to *flat gut* lesions. Differentiation from celiac disease is made by the absence of antiendomysial or anti-tissue transglutaminase antibodies (see Chapter 259, Gluten-Sensitive Enteropathy [Celiac Sprue]).

Again, the most common findings in CMPA are colitis findings, such as blood and mucus in the stool. Allergy is the most common cause of rectal bleeding among infants younger than 6 months. Rectal bleeding or guaiac-positive stools are among the most common symptoms in infants with formula sensitivity. A significant number of these infants experience straining or discomfort with stools.

In rare instances, some infants can exhibit severe enterocolitis. Profuse vomiting and/or diarrhea can lead to shock, anemia, and methemoglobinemia. Patients with milk protein-induced enterocolitis may be predisposed to a severe, rare form of enterocolitis to solid food antigens later in life. These children can develop severe reactions to food proteins considered to be of low allergenicity.

### Soy Protein Allergy

Among infants with enterocolitis caused by cow's milk allergy, 30% or more had similar reactions to soy-based formula. The clinical features of soy protein allergy are similar to those of CMPA discussed previously, including esophagitis, gastritis, enteritis, and colitis. In general, soy allergies are much less common than cow's milk allergies. Only 12% of all patients with CMPA will have concomitant allergy to soy protein.

### Human Milk Allergy

Infants who are breastfed may develop the same manifestations as patients who are formula fed, exhibiting either allergic colitis or evidence of esophagitis, gastritis, or enteritis; the most common seems to be colitis. These patients are often asymptomatic or may show significant irritability as a manifestation of their disease, with either occult blood or obvious rectal bleeding.

### Laboratory Abnormalities in Gastrointestinal Food Allergies

The results of IgE determinations and RAST (Radioallergosorbent test) to detect these IgE antibodies specific

for milk and soy proteins usually are negative, suggesting that the immunologic mechanism occurs by means of a non-IgE (T-cell-mediated) mechanism. A significant number of these patients also have a concomitant transient hypogammaglobulinemia or hypoalbuminemia caused by protein-losing enteropathy; treatment of the milk or soy allergy or other food allergy results in normalization of serum proteins. In addition, infants with formula allergy may not necessarily have elevated eosinophils in the blood, but typically will demonstrate an eosinophilic infiltration in GI biopsies. Reports indicate that more than 20 eosinophils per high-power field on rectal biopsy specimens is suggestive of an allergic cause for colitis. However, eosinophilic infiltration is a nonspecific finding that can occur in any inflammatory lesion of the GI tract, including infection.

### Management

Treatment of food allergy includes primary prevention to prevent sensitization to proteins. The previous recommendations of the American Academy of Pediatrics were revised in 2008 and are listed in Box 256-2. The most recent report from the GINI (German Infant Nutritional Intervention) study shows that the exclusive use of a partial or extensive hydrolysate formula significantly decreases rates of atopic dermatitis. Additional evidence for the benefit of partially hydrolyzed formulas for primary prevention has been recently supported by a meta-analysis and an accompanying editorial. Secondary prevention involves preventing recurrence of symptoms once they occur by removing specific food

#### BOX 256-2 American Academy of Pediatrics Recommendations for Prevention of Allergy

- Nutritional interventions are largely limited to infants at high risk of developing allergy (ie, infants with at least 1 first-degree relative with allergic disease).
- There is evidence that compared to intact cow's milk protein formula, exclusive breastfeeding for at least 4 months prevents or delays the occurrence of atopic dermatitis, cow's milk allergy, and wheezing.
- There is modest evidence that atopic disease may be delayed or prevented by the use of extensively or partially hydrolyzed formulas compared with intact cow's milk formula, particularly for atopic dermatitis.
- There is little or no current convincing evidence that the timing (delaying) of introduction of complementary foods beyond 4 to 6 months of age prevents the occurrence of atopic disease.
- There is no convincing evidence for the use of soy formula for allergy prevention.
- Current evidence does not support maternal dietary restrictions during pregnancy or lactation.

From Greer FR, Sicherer SH, Burks AW; American Academy of Pediatrics Committee on Nutrition and Section on Allergy and Immunology. Effects of early nutritional interventions on the development of atopic disease in infants and children: the role of maternal dietary restriction, breastfeeding, timing of introduction of complementary foods, and hydrolyzed formulas. *Pediatrics*. 2008;121(1):183-191.

allergens from the diet to ameliorate symptoms. Secondary prevention is accomplished with either extensively hydrolyzed formulas or elemental formulas. Categories of formulas are listed in Table 256-1, and a comparison of partial versus extensive hydrolysates appears in Table 256-2.

### Cow's Milk or Soy Protein Allergy

Many choices are available for formula, and the primary care physician should be familiar with the different protein bases.

Once the formula-fed infant either is suspected of having, or has been diagnosed as having, a specific protein allergy, the infant initially should be fed a hypoallergenic formula. The choice of formula will depend on the formula the patient is taking at the time of diagnosis. If the patient is taking a milk-based or soy-based formula, then starting with an extensively hydrolyzed casein hydrolysate formula, such as Alimentum, Nutramigen, or Pregestimil, is appropriate. A partially hydrolyzed whey formula may be helpful in reducing the risk of CMPA, but should not be used as treatment of existing allergy symptoms. Among partially hydrolyzed formulas, Good Start has been studied extensively but Gentlease has not.

The allergy may last as little as 3 to 12 months; therefore, this period is one of trial and error as the patient is gradually retried on the previously proved allergen.

Approximately 10% to 15% of infants placed on casein hydrolysate formula still have a persistent sensitivity as evidenced by continual guaiac-positive stools or overt GI bleeding. Many of these patients respond to the L-amino acid formulas, such as Neocate and Elecare. These formulas are expensive and should be used only when persistent sensitivity to all other formulas is well documented.

Milk or milk products from animals other than cows have also been used anecdotally. An example is sheep's or goat's milk. A risk of using such a product is the possible cross-reactivity between cow's milk and sheep's or goat's milk proteins, as well as nutrient deficiencies (ie, folate deficiency in goat's milk).

Of note, studies have examined the long-term growth affects of using various types of formulas (including partial and extensive hydrolysates) on children during the first 16 weeks of life. In a prospective study following German children, there does seem to be a slowing of body mass index (BMI) in the first year of life for infants on extensively hydrolyzed formulas when compared to other types of formulas and breast milk. However, no appreciable growth differences among these children were noted when followed up to 10 years of age.

Treatment in breastfed infants who are sensitive to mother's milk and present with rectal bleeding involves persuading the mothers to avoid cow's milk and soy products, but not all infants will respond to this

**Table 256-1** Nonstandard Infant Formulas

PROTEIN SOURCE	ALLERGENICITY	EXAMPLES
Soy protein with L-methionine	—	Bright Beginnings Soy, Good Start Supreme Soy, Isomil Advance, Enfamil Prosobee
Partially hydrolyzed whey	—	Good Start Supreme
Partially hydrolyzed casein, partially hydrolyzed whey	—	Gentlease
Casein hydrolysate	Hypoallergenic	Alimentum, Nutramigen, Pregestimil
Amino acid base	Nonallergenic	Neocate, Elecare

**Table 256-2** Soy vs Partial vs Extensive Hydrolysates vs L-Amino Acid Formulas

CATEGORY	SOY	PARTIALLY HYDROLYZED <sup>a</sup>	EXTENSIVELY HYDROLYZED <sup>b</sup>	L-AMINO ACID
Decreases protein sensitization	No	Yes	Yes	Yes
Treatment for established CMPA	No	No	Yes	Yes
Type of formula	Routine	Routine	Specialty	Specialty
Cost	Comparable with standard cow's milk	Comparable with standard cow's milk formula	3 to 4 times more costly than standard	Even more expensive than extensively hydrolyzed formula
Palatability	Comparable with standard	Comparable with standard	Less than standard	Less than standard formula

CMPA, Cow's milk protein allergy.

<sup>b</sup>Extensively hydrolyzed casein.

measure. Strict maternal diet avoidance of cow's milk, soy, and other potentially allergenic foods can be very challenging and lead to maternal nutritional deficiencies and weight loss. Mothers should be told that, by far, most infants who show sensitivity to foods the mother is eating do not have severe disease. Therefore, breastfeeding can be continued unless the symptoms are significant. Mothers who exclude multiple foods from their diets should consider vitamin and calcium supplementation. Sometimes using a hypoallergenic formula may be worth a trial to determine if the infant's symptoms disappear.

## EOSINOPHILIC GASTROINTESTINAL DISORDERS

Eosinophilic (or allergic) GI disorders (EGIDs) are a family of diseases characterized by the abnormal infiltration of the GI tract with eosinophils. EGIDs are subdivided into the specific anatomic area of inflammation within the GI tract, such as eosinophilic esophagitis (EoE), eosinophilic gastroenteritis, and eosinophilic colitis. With the exception of EoE, EGIDs are further classified by the depth of GI involvement into the categories of mucosal disease, muscular disease, and serosal disease.

For primary or allergic EGIDs, patients cannot have other causes of eosinophilic infiltration such as hypereosinophilic syndrome or parasitic infection, or reactive-type causes of inflammation such as inflammatory bowel disease, celiac disease, nutritional deficiencies, or neoplasms.

### Incidence

Although allergic gastroenteropathies were previously thought to be rare, EoE has become well recognized. Incidence is 4 in 10,000, but this may be underestimated because all incidence studies are based on referrals. The increased incidence seems to be the result of a combination of a higher index of suspicion and a true increase in pediatric allergy. Interestingly, the prevalence of EoE in children has been found to vary among certain populations: it was found to be 4% among patients with celiac disease in one cohort study. Meanwhile, the incidence of the rarer forms of EGIDs is not well characterized.

### Etiology

Causes for EGIDs have included sensitization to aeroallergens, autoimmune processes, ingested food allergies, and predisposition as a result of severe reflux or cutaneous atopy.

### Pathologic Considerations

IgE-dependent and IgE-independent mechanisms are thought to be involved in the pathogenesis of these conditions. The presence of peripheral eosinophilia, systemic allergies, elevated IgE levels, and therapeutic response to steroids indicates an allergic basis for this disease in some patients. Indeed, more than 50% of patients with EGID have a personal history of allergy, such as eczema, asthma, allergic rhinitis, or multiple food sensitivities.

## Clinical Manifestations

Patients with EoE have variable manifestations. Symptoms may include a feeding disorder, abdominal pain, or vomiting. Young children may have symptoms mimicking those of gastroesophageal reflux, but they usually have normal pH probe studies and fail to respond to antireflux medications. Older children may have dysphagia for solids or food impaction. A landmark study in 1995 involved a group of children previously diagnosed as having severe reflux that was unresponsive to medical and often surgical treatment. Esophageal biopsy specimens showed up to 100 eosinophils per high-power field. Allergies to multiple foods were found using a combination of prick skin tests and food challenges. The patients' symptoms resolved on an elemental diet. Follow-up biopsy specimens showed marked reduction in symptoms and esophageal eosinophils. Follow-up studies have corroborated these findings.

The other EGIDs have symptoms that vary with the anatomic site of eosinophilia and the depth of eosinophilic infiltration. Features are listed in Box 256-3. For example, mucosal disease causes dysphagia and heartburn if limited to the esophagus; nausea, bloating, and vomiting if involving the stomach; protein-losing enteropathy, malabsorption, and diarrhea if involving the small bowel; and bloody stools if involving the colon. In children, mucosal disease can often lead to anemia and growth failure. In submucosal or muscular disease, prominent inflammation in the stomach antrum can lead to pyloric obstruction. In serosal disease, which causes eosinophilic ascites, symptoms resemble peritonitis. The latter 2 types are less common in children. Because EGIDs have no classic symptoms, they can go undetected for several years. Furthermore, whether these entities are variants of similar disease processes or distinctly different conditions remains to be determined.

## Differential Diagnosis

The diagnosis of EGID is based on clinical features as well as laboratory and radiographic findings. Endoscopy is essential to confirm a diagnosis; therefore,

### BOX 256-3 Features of Eosinophilic (Allergic) Gastroenteritis<sup>a</sup>

#### MUCOSAL FORM

- Nausea, vomiting, colicky abdominal pain, diarrhea
- Occult blood loss, iron deficiency anemia
- Protein-losing enteropathy leading to hypoalbuminemia
- Failure to thrive/growth failure

#### MUSCLAR (TRANSMURAL) FORM

- Obstructive symptoms, mimicking pyloric stenosis or thickening of the gastric outlet

#### SEROSAL FORM

- Eosinophilic ascites

<sup>a</sup>Approximately 75% of affected patients have peripheral eosinophilia (with all 3 types).

collaboration with a pediatric gastroenterologist is necessary. A pediatric allergist can help direct specific testing for allergy.

For EoE, diagnosis is based on a typical patient or family history of allergy, an evaluation to rule out reflux, typical eosinophilic infiltration of the esophagus on the biopsy specimen, and allergy testing. Because the mechanism of allergic GI diseases is likely on a spectrum between immediate hypersensitivity and cell-mediated immunity, the value of any single test is variable. However, confirmation of food allergy is recommended, because 50% to 90% of suspected food allergies are not substantiated. Methods that collectively may play a role in the identification of food allergens include skin puncture test, directed IgE testing, food elimination, and oral food challenges. Peripheral eosinophilia occurs, and an elevated IgE level is a variable finding. Their absence does not rule out EoE. Radiographic studies, including an esophagram, may show thickened folds or a narrowing of the esophagus. On endoscopy, the mucosa may seem grossly normal, but suggestive findings are often apparent, especially the classic ringed or furrowed esophagus and white exudates (seen exclusively in EoE). Although scattered eosinophils are normal throughout the rest of the GI tract, they are pathologic when seen in the esophagus. In the past, eosinophils in the esophagus were attributed to reflux. Current research shows the esophageal eosinophilia in reflux is mild (<15 eosinophils per high-power field) and usually limited to the distal esophagus. In EoE, the eosinophilia is severe (>15 eosinophils per high-power field) and can involve most of the length of the esophagus.

The evaluation of other forms of EGID is similar, with identification of concurrent forms of allergy. Allergy testing, as mentioned, can be positive for multiple food allergies. Laboratory studies may also include elevated peripheral eosinophils and IgE levels, as well as hypoalbuminemia and low immunoglobulin levels caused by malabsorption and protein-losing enteropathy. If long-term blood loss exists, then laboratory studies may show iron-deficiency anemia. Radiographic studies, including an upper GI tract study, may show thickened folds caused by edema in the stomach or possibly gastric outlet obstruction. A small bowel follow-through may show an edematous or nodular small bowel. Although no strict criteria have been clearly established for nonesophageal forms of EGIDs, in general, less than 50 eosinophils per high-power field is considered consistent with EGID. Gastric abnormalities, found more commonly in the antrum, have been described as being consistent in the mucosal form of the disease. Typical findings include gastritis, with destruction and regeneration of gastric glands and surface epithelium, as well as marked eosinophilic infiltration. If the allergic gastroenteropathy involves the small bowel, then the lesions are in a patchy distribution, ranging from areas of normal mucosa to a flat villus lesion. Eosinophilic infiltration may be mild or marked.

### Management

Because allergic gastroenteropathies have variable manifestations and lapsing and remitting courses,

management must be individualized with the assistance of a pediatric gastroenterologist and allergist. Unless concomitant gastroesophageal reflux exists, patients do not usually respond to histamine-2 blockers or proton-pump inhibitors. Food diaries can be confusing; for example, if the patient experiences a delayed hypersensitivity reaction, then symptoms are not apparent when foods are ingested, but instead occur days later. However, if foods are identified as positive using a combination of tests for immediate or delayed hypersensitivity and food challenges, then these foods should be eliminated from the diet. The most common foods implicated are, in order, milk, egg, soy, corn, and wheat, although several foods may be found to cause symptoms. Dietary elimination of these allergens may alleviate most of the symptoms. In EoE, identification of individualized allergens has been demonstrated through a 6-food elimination diet in which several common allergens are collectively avoided (cow's milk, soy, wheat, egg, peanut, and seafood). Subsequently, each food is serially reintroduced followed by a repeat endoscopy in an attempt to identify causative antigens of inflammation. Some patients require complete dietary elimination via an L-amino acid-based formula. The advantage of dietary management is good rates of cure. However, severely restrictive diets may be difficult for children and may create social and behavioral issues. Exclusive reliance on specialized formulas can be extremely expensive. In instances of severe disease where elemental formulas are necessary, but refused orally, tube feeding (nasogastric or gastrostomy) may be considered.

For patients who are unable to follow a restrictive diet, corticosteroid therapy may be required intermittently. Systemic steroids have the advantages of quick improvement of symptoms and normalization of tissue on biopsy specimens. However, they cannot be used on a long-term basis, and eosinophilic infiltration and symptoms can recur after discontinuing therapy. Topical steroids, such as swallowed fluticasone propionate, improve symptoms and histologic findings in EoE. Oral budesonide, when mixed into a viscous, slurry form, is also effective, especially in younger patients who have trouble swallowing fluticasone. Again, symptoms and baseline histologic findings may return upon discontinuation. Topical treatment may be associated with esophageal candidiasis. Oral cromolyn sodium (Gastrochrome) has not been proved helpful in EoE but may have a beneficial role in eosinophilic gastroenteritis. Leukotriene receptor antagonists may be beneficial in eosinophilic gastroenteropathy in improving symptoms, but they do not change histologic findings. Symptomatic strictures resulting in food impactions or severe dysphagia may require endoscopic dilatations, and pyloric obstructive disease may require surgery. If patients have other symptoms of allergy or atopy, then these should be addressed as well.

### Prognosis

The natural history of EoE remains unclear. Among adults with misdiagnoses of reflux who were eventually found to have EoE, some develop strictures requiring dilation. The esophagus can be friable, tearing

with the mere passage of an endoscope. The possible evolution to Barrett esophagus remains to be studied.

Although extensive follow-up studies are lacking, evidence indicates that the EGIDs are lifelong conditions with remissions and exacerbations, often requiring careful dietary manipulation and intermittent steroid therapy. Preliminary data also suggest that younger adolescents go through a phase in which they are much better able to tolerate foods to which they were previously sensitive. If the EGID produces significant malabsorption, then osteoporosis may occur.

## CONCLUSION

GI food allergy is an immunologic response to an antigen often leading to nonspecific GI symptoms, depending on the anatomic location of involvement. Such GI allergy can involve a specific allergen, as is the case in cow's milk or soy protein allergy found in younger children, or multiple food sensitivities, as found in allergic or eosinophilic GI disease. The underlying immune mechanisms for cow's milk or soy protein allergy are thought secondary to non-IgE mechanisms, whereas EGIDs involve a combination of immediate hypersensitivity and non-IgE mechanisms. The diagnosis of cow's milk or soy protein allergy is largely clinical. For the diagnosis of EGIDs, allergy, laboratory, and radiographic testing may be supportive with confirmation of disease made through GI biopsies via endoscopy or colonoscopy. The mainstay of therapy is identification and avoidance of allergens. For EGIDs, medications and steroids often play a role in management. For specific allergens, such as cow's milk or soy protein, the condition is often self-limited. In the case of EGIDs, the condition is often a lifelong disease with a remitting and relapsing course.

### WHEN TO REFER

- Poor weight gain
- Immediate GI response after particular food or foods
- Incomplete response to exclusion or elemental diet
- Multiple food allergies
- Multiple allergic symptoms
- Malabsorption or protein-losing enteropathy
- Gastroesophageal reflux disease recalcitrant to appropriate therapy
- Suspicion of eosinophilic esophagitis

### WHEN TO ADMIT

- Anaphylaxis
- Severe malnutrition

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 257 GASTROINTESTINAL OBSTRUCTION

Jeffrey S. Mino, MD; Rosebel Monteiro, MD; Anthony Stallion, MD

Gastrointestinal obstruction (GIO) during infancy, childhood, and adolescence is relatively uncommon, but often presents a diagnostic challenge (Table 257-1). Obstructions that occur distal to the pylorus are potential surgical emergencies, and the younger the patient, the more ominous the probable cause and the more urgent the required therapy. Therefore, the pediatrician must be continually alert for a GIO to facilitate early diagnosis and thus prevent significant morbidity.

## EVALUATION

### History

The symptoms and signs of a GIO (Table 257-2, Figure 257-1) vary considerably but involve the following, either singly or in combination: vomiting (often bilious), abdominal pain, abdominal distention (see

**Table 257-1** Summary of Pediatric Gastrointestinal Obstruction and Surgical Intervention

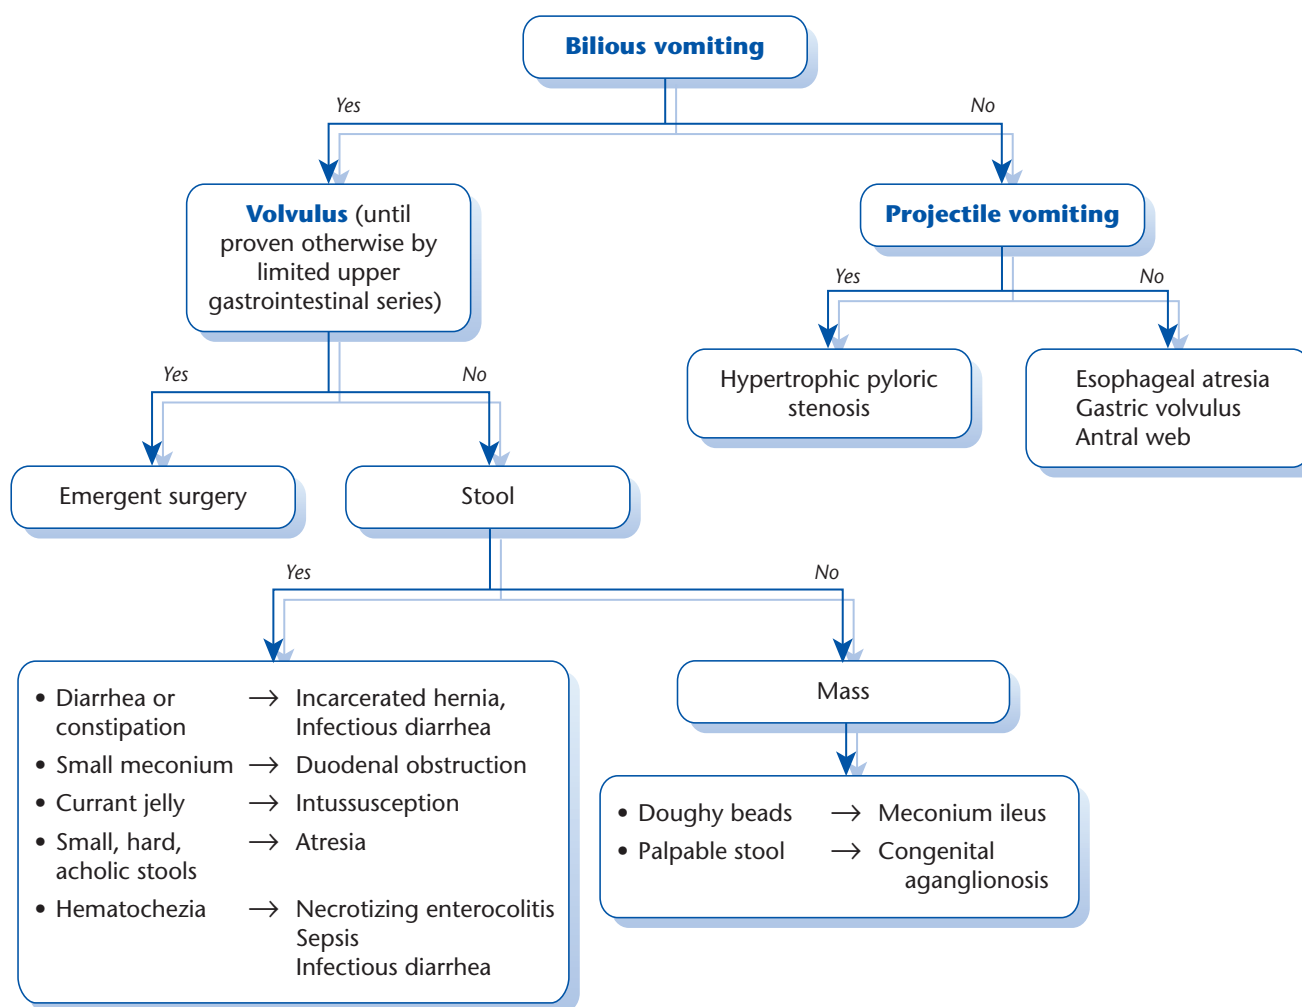

DISEASE	FREQUENCY	AGE	SURGICAL TREATMENT	COMPLICATIONS	PROGNOSIS
Esophageal atresia	1/3,000–1/5,000	Neonates	Division of fistula, anastomosis of esophageal ends ± gastrostomy	Aspiration, leak, GERD, strictures	Associated with cardiovascular abnormalities, imperforate anus, duodenal obstruction, malrotation If no cardiac anomaly, >95% survival
Gastric volvulus	Rare	Any	Gastropexy and gastrostomy tube ± resection	Sepsis, leak	If no necrosis—good; with necrosis—high mortality
Antral web	Rare	Infants	Divide web modified pyloroplasty, gastrostomy	Leak	Good
Hypertrophic pyloric stenosis	1/250	Neonates, infants	Pyloromyotomy	Incomplete, mucosal leak	Good
Volvulus	1/500	Infants, but 20% >1 yr of age	Detorsion of mesentery, divide Ladd bands, intestinal resection	Leak, sepsis, short-gut syndrome	If no necrosis—good; with necrosis—guarded
Intestinal atresia	1/2,700	Neonates	Resection and anastomosis	Strictures, leak, poor gut motility	50% associated with other anomalies
Meconium ileus	1/2,800	Neonates	Enema, intestinal cleansing through enterotomy, possible resection	Sepsis, malnutrition	Associated with cystic fibrosis immediately after surgery—good; long-term—poor
Hirschsprung disease	1/4,000	Neonates	Colostomy, delayed pull-through procedure	Sepsis, incontinence	Good
Imperforate anus	1/4,000	Neonates	Colostomy, delayed pull-through procedure	Sepsis, incontinence	High defects—guarded; low defects—good
Incarcerated hernia	1/1,000	Any	Reduction, possible intestinal resection	Sepsis	Good to guarded
Intussusception	1/1,000	3 mo–3 yr	Air-enema reduction ± resection	Ischemic bowel, leak, recurrence	May have pathologic cause in older children; good if no necrosis; with necrosis, potential short-gut syndrome
Duplication cyst	Rare	Any	Complete excision and anastomosis	Bile duct injury	Possible late malignant transformation
Meconium plug	1/500–1/1,000	Neonates	Rectal stimulation, enema	Leak, acute dehydration, shock	Associated with CF, small left colon, rectal aganglionosis
Functional obstipation of prematurity	Rare	Neonates	Colostomy for severe cases	Sepsis	Good

CF, Cystic fibrosis; GERD, gastroesophageal reflux disease.

Table 257-2

## Clinical Findings for Pediatric Gastrointestinal Obstruction

FINDINGS						
CAUSE	VOMITING	PAIN	STOOL PATTERN	DISTENTION	BOWEL SOUNDS	TENDERNESS
						ABDOMINAL MASSES
Esophageal atresia	Nonbilious (saliva)	No	Normal meconium	No	Absent to normal	No
Gastric obstruction	Nonbilious (curdled formula)	Severe with gastric volvulus; none with antral web	Normal meconium	Epigastric	Absent to normal	No
Hypertrophic pyloric stenosis	Nonbilious, projectile	No	Constipation (dehydration)	Epigastric	Hyperactive (epigastric)	Yes (olive-sized mass)
Duodenal obstruction	Bilious	Minimal	Small meconium stool	Epigastric	Absent to normal	No
Volvulus	Bilious	Severe	Hematochezia	Epigastric to generalized	Hyperactive	No
Jejunioileal atresia	Bilious	No	Small, hard, light-colored meconium stool	Generalized	Variable	No
Intussusception	Bilious	Yes (crampy)	Currant jelly stool	Generalized	Hyperactive	Yes (sausage shaped)
Meconium ileus	Bilious	No	Obstipation	Generalized	Variable	Yes (doughy beads)
Meconium plug	Bilious	No	Obstipation	Generalized	Variable	No
Congenital aganglionosis	Bilious	No	Obstipation, constipation, and intermittent diarrhea	Generalized	Hyperactive	Palpable stool
Obstipation of prematurity	Bilious	No	Obstipation	Generalized	Hyperactive	No
Incarcerated inguinal hernia	Bilious	Yes	Diarrhea or constipation	Generalized	Hyperactive	Inguinal or scrotal
Imperforate anus	Bilious	No	Obstipation	Generalized	Hyperactive	No

**Figure 257-1** Clinical findings in pediatric gastrointestinal obstruction.

Chapter 124, Abdominal Distention), change in bowel habits, fever, abdominal tenderness, or a palpable abdominal mass. The presence or absence of each of the key symptoms and signs, along with the child's age, are important clues to etiology.

### Vomiting

Vomiting is a ubiquitous symptom, the cause of which is most often not GIO. However, vomiting can be a sign of obstruction, particularly when marked by certain characteristics.

A small amount of nonbilious, nonprojectile vomitus by an infant is unlikely to indicate a GIO; it commonly denotes a benign, self-limited form of regurgitation or gastroesophageal reflux (chalasia). Gastroesophageal reflux can be ruled out in most cases by commonly accepted diagnostic tests such as a 24-hour pH probe study or a nuclear medicine milk reflux scan. However, nonbilious, nonprojectile vomitus in the newborn can also be associated with an esophageal obstruction (atresia). The neonate may have copious, frothy bubbles of mucus that cause rattling respirations,

coughing, choking, and cyanosis. Respiratory distress caused by tracheal aspiration of saliva retained in the upper esophagus or aspiration through the commonly associated tracheoesophageal fistula proximal or distal to the atresia can be associated with this anomaly. An esophageal block encountered during attempts to pass a size 8- or 10-French transoral soft catheter approximately 17 cm into the stomach denotes esophageal atresia.

Esophageal atresia and the rare entity of pediatric gastric volvulus are the 2 most likely neonatal conditions in which a congenital or early acquired esophageal obstruction is likely to be encountered. Acute gastric volvulus, unlike esophageal atresia, is often accompanied by severe pain and can be associated with signs of shock, chest pain, dysphagia, dyspepsia, and acute respiratory distress. Nonbilious vomiting can also be produced by the rare anomaly of a complete or incomplete gastric antral web. Frequently, this diagnosis is a delayed one that occurs in late infancy and is associated with failure to thrive.

The more dramatic projectile, nonbilious vomiting of early infancy is associated with the semi-urgent medical conditions of dehydration and electrolyte disturbances as a result of congenital hypertrophic pyloric stenosis. The electrolyte abnormalities are typically a hyponatremic, hypochloremic, hypokalemic contraction metabolic alkalosis with a possible late paradoxical aciduria (see Chapter 321, Pyloric Stenosis.)

Bilious vomiting, usually nonprojectile, is a more ominous problem and denotes GIO below the level of the ampulla of Vater. Concern arises because of the possibility of intestinal malrotation with a complicating midgut volvulus, which can produce GIO with ischemia and subsequent bowel necrosis within a few hours. Although a premature infant who has an immature pyloric sphincter can have bilious regurgitation without obstruction, especially when it is associated with an ileus related to an underlying septic process, the threat of intestinal vascular compromise caused by an underlying volvulus requires immediate radiologic examination for diagnosis. Clinical signs of peritonitis preclude radiologic study for diagnosis, and an immediate exploratory laparotomy is necessary. Usually an upper gastrointestinal (GI) radiographic series is the diagnostic study of choice in less ill neonates, although the diagnosis may also be made by ultrasound. Other causes of bilious vomiting in the neonate and infant include duodenal, jejunal, and ileal atresias; duodenal stenosis caused by an annular pancreas or Ladd bands (colonic peritoneal bands crossing the duodenum) associated with malrotation; meconium ileus; colonic atresia; congenital aganglionosis of the colon (Hirschsprung disease); and imperforate anus.

An infant or older toddler who has bilious vomiting may have a GIO produced by a foreign body ingestion, an incarcerated hernia, intussusception, or previously unrecognized malrotation with associated volvulus. The causes of bilious vomiting in an adolescent can include incarcerated hernias, postoperative adhesions, meconium ileus equivalent associated with cystic fibrosis, acute inflammation (appendicitis and pelvic inflammatory disease), chronic inflammation (regional ileitis or ulcerative colitis), and in rare instances, intermittent inflammation (celiac sprue). At this age, malrotation is less likely. In less developed countries, masses of worms, especially *Ascaris lumbricoides*, and tuberculosis also can be a cause of obstruction. A significant number of all patients who have persistent bilious emesis will have an underlying pathologic abnormality requiring early diagnosis and definitive surgical treatment.

Vomit containing small amounts of blood may be observed in infants who have congenital hypertrophic pyloric stenosis caused by gastric irritation as a result of repeated emesis. In rare cases, hematemesis with larger amounts of blood is associated with GIO. This may be found in the uncommon occurrence of an acute peptic ulcer, resulting in obstruction in a newborn or in an older, chronically stressed infant or child. Infection with *Helicobacter pylori* is also a potential cause of peptic ulcer disease in children, again more so in developing countries.

### Abdominal Pain

Abdominal pain, which may cause inconsolable crying or irritability in an infant, usually accompanies GIO. The pain is likely to be crampy or intermittent, and it results in crying and flexion of the legs to the abdomen interspersed with periods of decreased levels or absence of distress. This sign is exemplified best by the toddler who has an intussusception. However, approximately 10% of children who have intussusception will have lethargy as their only symptom. A complete or partial obstruction of the intestine produces acute intermittent abdominal pain because of an increase in the force and frequency of peristaltic waves in the bowel proximal to the obstruction. Within a matter of hours, the pain becomes constant and is caused by intestinal distention, peritoneal inflammation, or both. Bowel wall edema ensues, increasing the degree of obstruction and causing a progression of changes that place the intestine at further risk for ischemic damage.

### Stool

Obstipation in a newborn is an important finding. Full-term, healthy newborns spontaneously pass meconium within the first 24 hours of life. With premature newborns, those who are small for gestational age, and babies of mothers with diabetes, a delay of up to 72 hours may occur before the initial stool is passed. The initial bowel movement may also be delayed if pregnancy is complicated by maternal drug abuse (narcotics such as morphine), drug therapy (eg, magnesium sulfate for toxemia), or neonatal stress (hypoxemia or sepsis).

Atresias of the proximal portion of the intestinal tract do not usually cause obstipation except for those involving the most distal terminal ileum; however, the meconium passed by these infants is usually sparse and lighter in color, and it may be hard and dry. The differential diagnosis of newborn obstipation includes congenital aganglionosis of the colon (Hirschsprung disease), meconium ileus (with underlying cystic fibrosis), meconium plug syndrome (30% of these are associated with congenital aganglionosis of the colon or cystic fibrosis), small left colon syndrome, colonic atresia, imperforate anus, and, in rare cases, rectal atresia.

Strictures that occur as a result of episodes of neonatal necrotizing enterocolitis or intestinal surgery, as well as extrinsic compression of the GI tract caused by congenital cysts, intestinal duplication, inflammatory masses, or malignancies, produce obstipation or constipation in an older infant or child.

Particularly in neonates and infants, diarrhea or alternating diarrhea and constipation can occur as a sign of functional GIO or as a partial or intermittent GIO. Congenital colonic aganglionosis, intussusception, or intermittent volvulus may also be causes. The latter 2 conditions frequently occur along with hematochezia or melena.

Hematochezia, or grossly bloody stools, in association with GIO symptoms, indicates intestinal vascular compromise. It occurs most commonly in infants who have an intussusception or volvulus. The so-called *currant jelly stools* of intussusception result from the

admixture of blood and mucus and are a sign of superficial mucosal sloughing, but they can also accompany a full-thickness necrosis of the bowel wall. Occasionally, darker (mahogany to black), melena-type stools resulting from a more proximal intestinal bleeding site are noted, with the same potentially dire causes. In infants without grossly bloody stools, occult blood is present in up to 75% of intussusception cases. Thus, a hemoccult test should be performed in all infants with altered mental status.

### Physical Examination

With a history of vomiting, an infant first needs to be evaluated for signs of dehydration. Inspection of the anterior fontanel, rate and intensity of distal pulses, level of consciousness, perfusion of the extremities, and condition of the mucous membranes can aid in determining hydration status. When GIO is suspected, the physical examination of the abdomen includes evaluation for distention, which is likely to be prominent if the obstruction is distal to the duodenum (see Table 257-2 and Figure 257-1). Gastric obstruction caused by a congenital antral web, hypertrophic pyloric stenosis, or duodenal atresia produces only mild to moderate epigastric distention; distal intestinal atresias or other forms of lower GIO produce generalized distention. The presence or absence of abdominal distention does not aid in the diagnosis of a potential underlying midgut volvulus because the obstruction may be at the level of the duodenum, with few air- and fluid-distended bowel loops present.

Abdominal auscultation should be performed before any other aspect of abdominal examination. An effort should be made to listen to all the abdominal quadrants. Hyperactive, high-pitched, *tinkling* bowel sounds heard in rushes are diagnostic of a complete GIO. However, bowel sounds are often normal early, only becoming diminished or absent late in obstruction.

If the abdomen is moderately to grossly distended, then a mild amount of tenderness or discomfort with palpation is to be expected because pressure applied to gas- or fluid-filled loops of bowel causes pain. However, marked, diffuse tenderness clearly indicates an accompanying peritoneal inflammation. This inflammation (or peritonitis) in the setting of GIO indicates ischemia of the bowel wall with possible necrosis and demands immediate surgical evaluation and treatment. In this situation, diagnostic radiologic studies that use contrast material are contraindicated.

The presence of multiple *doughy*, compressible, mobile, nontender abdominal masses in a newborn who has GIO is associated with meconium ileus and indicates the presence of fecal impaction throughout the colon. On the other hand, a tender, palpable, immobile mass is most likely an area of cellulitis or abscess related to visceral perforation and is the result of necrotizing enterocolitis in infants or appendicitis or inflammatory bowel disease in children and adolescents. A non-tender, mobile mass that produces GIO symptoms is found with congenital intestinal duplication cysts or mesenteric cysts. A sausage-like mass in the right upper quadrant with absence of bowel in the right lower quadrant is pathognomonic of intussusception and is called the *Dance sign*. Malignancies in

the intestinal tract are rare and do not usually produce intestinal obstruction in infants and toddlers, but lymphomas may do so in older children. When they cause GIO, intestinal or mesenteric lymphomas in children older than 4 years of age commonly present as an intussusception. Additionally, an immunocompromised host who has a malignancy or acquired immunodeficiency syndrome may develop primary or secondary inflammatory lesions that lead to obstruction.

An incarcerated inguinal hernia is an important cause of GIO in children and adolescents. Detecting an inguinal hernia in an uncooperative, chubby infant is difficult and requires considerable patience and effort. Sedation with a tranquilizer, with or without an added narcotic analgesic, while keeping the child supine in the mild Trendelenburg position and applying an ice pack to the inguinal region may be helpful in the reduction of an incarcerated hernia. Medications must be used cautiously to prevent excessive sedation because vomiting and aspiration can occur. If possible, the hernia should be reduced gently and repaired later, when the effects of the GIO and local edema subside. If the hernia is reduced but left unrepaired, then recurrent incarcerations are likely, with the potential consequences of strangulation and necrosis of the bowel.

A rectal examination can often clarify the cause of GIO. In an infant who is suspected of having an incarcerated inguinal hernia, the pediatrician can often palpate the peritoneal side of the internal inguinal ring transanally and identify an exiting intraperitoneal structure. The rectal examination can be equally important in the diagnosis of any suspected colonic or distal GIO. Previously unsuspected perirectal or presacral pelvic masses (eg, hydrometrocolpos, appendiceal inflammatory mass, presacral teratoma) can be identified in this manner. Abnormal stool (as in the infant who has meconium plug syndrome) or blood (associated with intussusception or inflammatory bowel disease) can be detected during a rectal examination. In rare cases, an intraluminal rectal mass can be palpated, such as with a low-lying intussusception.

### Imaging Studies

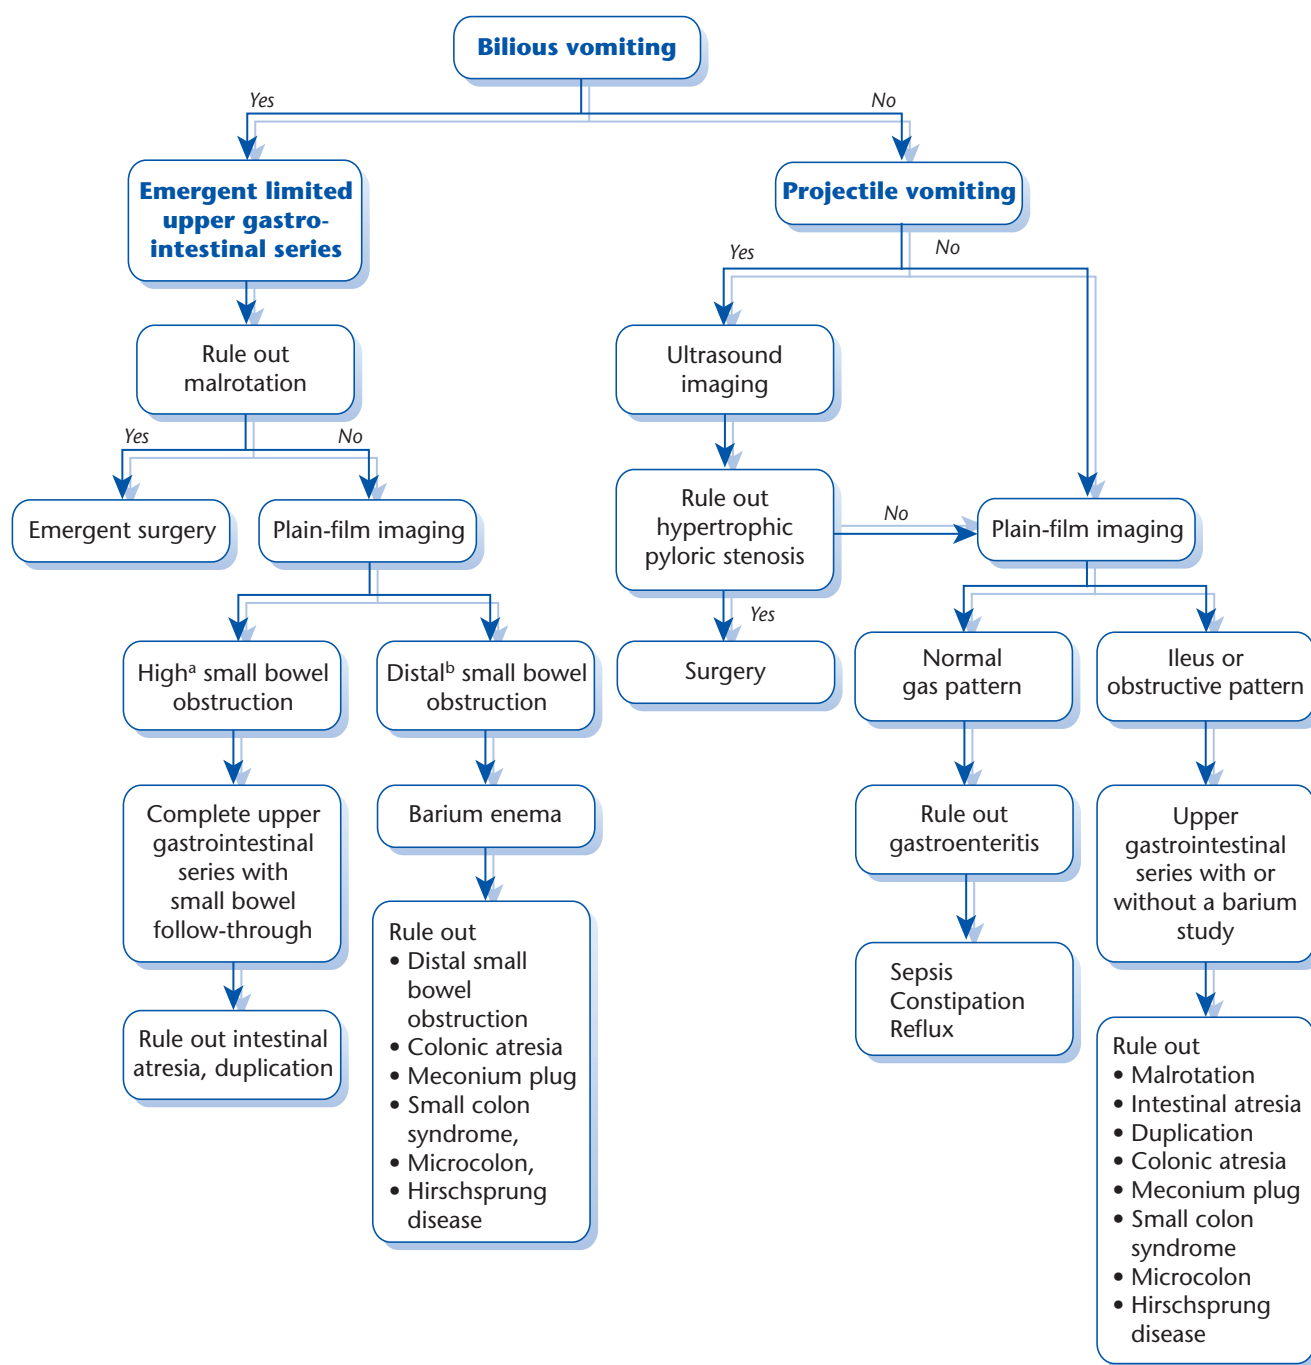

When deciding which radiologic tests to order, the physician must recall that estimated radiation exposure during the first 10 years of life poses a lifetime risk 3 to 4 times greater than exposure between the ages of 30 and 40 years. With the widespread use of prenatal ultrasound, GIO may be diagnosed before the birth of the child. In up to 40% of cases, findings such as polyhydramnios, an inability to identify the stomach, cystic abdominal lesions, and dilated loops of bowel strongly suggest the presence of an obstructive intestinal lesion. The prenatal diagnosis of GIO (ie, atresia, volvulus) alleviates the need for an emergent postnatal workup.

Table 257-3 and Figure 257-2 list radiographic diagnostic studies required for a child who has GIO and their expected findings; these studies are dictated by the results of the history and physical examination. A plain-film radiograph of the abdomen should be obtained for all children suspected of having GIO. Chest

**Table 257-3** Radiographic Findings for Common Causes of Pediatric Gastrointestinal Obstruction

CAUSE	FINDING					FURTHER STUDIES THAT MAY BE INDICATED
	DILATED AREA	AIR OR FLUID LEVELS	CALCIUM DEPOSITS	NON-CALCIUM OPACITIES		
Esophageal atresia	Esophagus (and stomach depending on type of fistula present)	Variable (usually gastric)	No	No	Esophageal air instillation	
Gastric obstruction	Stomach	Yes	No	No	Gastric barium instillation <sup>a</sup> Ultrasonography	
Hypertrophic pyloric stenosis	Stomach	Yes	No	No		
Duodenal obstruction	Stomach, duodenum (double bubble)	Yes	No	No	None	
Volvulus	Variable	Variable	No	No	Upper gastrointestinal series or barium enema	
Jejunioileal atresia	Stomach and small intestine	Yes	Yes (with prenatal perforation)	No	Barium enema to rule out nonrotation	
Intussusception	Stomach and small intestine	Variable	No	Yes (soft-tissue densities)	Ultrasonography, barium/air enema <sup>b</sup> , or both	
Meconium ileus	Stomach and small intestine	No	Yes (meconium peritonitis)	Yes (ground-glass appearance)	Water-soluble contrast enema <sup>c</sup>	
Meconium plug	Stomach to colon	Yes	No	No	Water-soluble contrast enema	
Congenital aganglionosis	Stomach to colon	Yes	No	No	Barium enema	
Obstipation of prematurity (short left colon syndrome)	Stomach to colon	Yes	No	No	Barium enema	
Incarcerated inguinal hernia	Stomach and small intestine	Yes	No	No	None	
Imperforate anus	Stomach to colon	Yes	No	No	Complete evaluation of genitourinary tract	

<sup>a</sup>Should be performed cautiously to avoid aspiration.<sup>b</sup>Should be performed cautiously to avoid bowel perforation.<sup>c</sup>May be therapeutic and diagnostic.

radiography can demonstrate the curling of a nasogastric tube or dilated pouch in esophageal atresia (Figure 257-3). In a newborn, air localized to the stomach and duodenum (double-bubble sign) is diagnostic of a duodenal obstruction (Figure 257-4). If no distal intestinal intraluminal air is seen, then the GIO is usually caused by an atresia; however, if even a small amount of air is found distally, then the diagnosis of a

malrotation with possible volvulus must be suspected. Use of an upper GI series to determine the relationship among the duodenum, the jejunum, and the ligament of Treitz, or a barium enema to ascertain cecal position, is necessary to rule out a malrotation or nonrotation of the intestine. The presence of even a large number of air-filled loops on the plain-film radiographic study of the abdomen does not eliminate the

**Figure 257-3** Plain-film radiograph demonstrating curling of nasogastric tube in esophageal atresia without tracheoesophageal fistula (*left*). Lateral radiograph with dilated air-filled esophageal pouch compressing the trachea (*right*).

need for a contrast study because a volvulus still is possible. In a child with volvulus, contrast study may show a corkscrew appearance projecting forward, away from the posterior abdominal wall; color Doppler ultrasound may show a distorted relationship of the superior mesenteric vessels in a spiral pattern. Visualization by barium enema of an *unused*, small-caliber distal colon (microcolon) in a normal position makes the diagnosis of intestinal atresia or meconium ileus more likely than acute volvulus.

Calcifications visualized by an abdominal radiograph in a neonate with suspected GIO are evidence of an intrauterine intestinal perforation (meconium peritonitis), which is often associated with intestinal atresia. The calcifications may be small, single, or multiple and scattered throughout the entire peritoneal cavity, or they may outline the peritoneal cavity (Figure 257-5). Cystic fibrosis may be the underlying disease producing such a manifestation.

Infants suspected of having hypertrophic pyloric stenosis usually do not require an upper GI series to confirm the diagnosis. The classic symptoms of upper abdominal peristaltic waves and a palpable, olive-sized mass in the mid to right upper quadrant is diagnostic. An experienced pediatrician or surgeon will be successful in palpating the olive-sized mass in approximately 80% to 90% of affected infants. An

abdominal ultrasound scan can aid diagnosis in cases in which the pyloric stenosis is suspected, but no palpable mass exists. Radiographic confirmation is needless, costly, and potentially hazardous because residual barium may remain in the dilated, obstructed stomach at the time of induction of anesthesia (see Chapter 321, Pyloric Stenosis).

An unusual presentation is possible, with nonbilious vomiting and no clinically palpable olive-sized mass, a normal abdominal ultrasound examination, and a normal upper GI contrast study. This sequence of events may lead to a long delay in diagnosing an underlying partial gastric antral web. Barium study of the upper GI tract may show a normal duodenal bulb with a proximal antral chamber between the web and the pylorus, known as the double duodenal bulb appearance. This situation can be clarified by esophagogastroduodenoscopy to identify and potentially divide the web. If the web cannot be treated safely during endoscopy, then open gastric antroplasty is effective.

Duplication cysts can occur anywhere in the GI tract, but most frequently in the ileum, followed by the stomach. Ultrasound is the most useful radiologic modality to diagnose enteric duplication cysts. The *rim* sign is composed of an echogenic inner rim of mucosa and hypoechoic outer rim of the muscle layer. Peristalsis

**Figure 257-4** Duodenal atresia. An upright radiograph of a 4-day-old girl with persistent vomiting since birth. The double-bubble sign is classic, showing the large gastric fluid-filled air bubble on the right and the similar duodenal bubble on the left. (From *Micro X-ray Recorder, Inc., Chicago, IL.*)

**Figure 257-5** Ileal atresia with meconium peritonitis. An upright radiograph of a 36-hour-old girl with persistent vomiting since birth. The numerous dilated loops of small bowel with fluid levels indicate atresia of the ileum; the calcification (arrow) is diagnostic of meconium peritonitis caused by prenatal rupture of the small bowel. (From *Micro X-ray Recorder, Inc., Chicago, IL.*)

of the cyst wall and septations also aid in the diagnosis of duplication cysts.

An abdominal radiograph of GIO in association with suspected cystic fibrosis (meconium ileus) often has a peculiar hazy pattern described as a *ground-glass* or *soap bubble* appearance (Figure 257-6). Gas may be absent in the right iliac fossa because of a meconium cyst. This pattern is caused by the abnormal meconium mixed with air that is inspissated in the bowel lumen. Occasionally, this hard, dense stool, palpable as multiple abdominal masses, appears on the radiograph as a chain of radiolucencies, known as the *string of beads* sign. Meconium ileus, as with ileal atresia, is associated with a complete GIO; however, air-fluid levels are rare in meconium ileus. Meconium ileus and meconium plug syndrome are 2 neonatal GIO conditions that can be diagnosed and frequently can be treated with a water-soluble contrast enema.

A neonate who is suspected of having meconium ileus, who has no evidence of perforation, and who is well hydrated can be given a water-soluble contrast enema cautiously by an experienced radiologist. This procedure identifies the inspissated meconium, localized to the distal ileum, and may free it from the bowel wall for spontaneous expulsion. This technique is limited in application and duration, with subsequent surgical therapy required in as many as 50% of infants treated in this way. Uncomplicated meconium plug

syndrome—a lower GIO lesion infrequently associated with cystic fibrosis, but occasionally associated with congenital aganglionosis—is also diagnosed and treated successfully with a barium enema. Unlike meconium ileus, the abnormal meconium in meconium plug syndrome is localized to the distal colon. Contrast enemas in either syndrome are contraindicated when evidence exists of intestinal vascular compromise or perforation such as peritonitis, free intraperitoneal air, or intraperitoneal calcification. With meconium peritonitis, sonography may show ascites with echogenic debris, abnormal cystic masses, and thickening and dilation of the bowel wall.

Older infants and toddlers suspected of having GIO produced by intussusception can be diagnosed using ultrasound, revealing a thickened segment of bowel telescoped in on itself. Doppler flow may be absent in this segment if bowel wall edema has increased pressure beyond that of arterial inflow, indicating that ischemia is occurring and urgent intervention is necessary. Enema administration in intussusception is both diagnostic and therapeutic. In the past, this was traditionally performed with the use of barium. The study was performed with a limited-pressure (3 feet) barium column, and the intussusception was slowly reduced by the hydrostatic pressure generated. Because of the potential hazard of a barium perforation, a surgical team had to

**Figure 257-6** Meconium ileus. An upright radiograph of a 2-day-old boy with abdominal distention since birth. The loops of distended bowel of varying size without fluid levels are filled with meconium shadows (radiolucent soap bubbles). (From *Micro X-ray Recorder, Inc., Chicago, IL.*)

**Figure 257-7** Aganglionic megacolon (Hirschsprung disease). An upright radiograph of a 2-day-old boy with distended abdomen who failed to pass anything rectally shows extreme distention of the colon with several fluid levels. (From *Micro X-ray Recorder, Inc., Chicago, IL.*)

be standing by. The procedure, which could be used in approximately 75% of patients, successfully reduced the intussusception in 85% to 90% of these cases.

Air enema reduction of the intussusception has become available and is now the treatment of choice in intussusception reduction. This technique consists of air insufflation of the rectum and colon using an inline pressure-limiting valve while maintaining fluoroscopic or sonographic observation to ensure that the reduction is under control. The advantages of this technique are, first, elimination of barium, with the threat of severe chemical peritonitis if a perforation inadvertently occurs; and second, possibly an improved mechanical advantage by using air reduction. Investigators have stated that repeated attempts at pneumatic reduction improve the success rate without adverse outcome. In addition, it should be noted that edema of the bowel wall may prevent reflux of contents even if successful reduction has occurred; therefore, the enema may be repeated in 6 to 8 hours to determine whether passage of contents is occurring, indicating the reduction was successful and the edema has decreased, allowing patency of the lumen. The patient always should be observed for 12 to 24 hours in the hospital after successful intussusception reduction.

Surgical reduction is required in cases that are unable to be reduced radiologically. Some experts have advocated the use of laparoscopy to aid in this

reduction. The diagnosis can also be made effectively by computed tomography (CT) if necessary, but ultrasound or enema are usually sufficient and harbor no or minimal risks associated with radiation. Thus, CT should be reserved for cases in which ultrasound is nondiagnostic, physical examination is unremarkable, and history is equivocal.

Congenital aganglionosis of the colon (Figure 257-7), or Hirschsprung disease, in infancy can be lethal if complicated by enterocolitis. Hirschsprung disease seldom produces total GIO, which, when present, must be treated as an emergency. The initial diagnosis is made based on clinical suspicion because it cannot be verified by noninvasive diagnostic procedures. A barium enema or anorectal manometry reflecting an absent rectosphincteric reflex is often helpful in diagnosing Hirschsprung disease in older children, but either a rectal mucosal or full-thickness rectal wall biopsy specimen is required to confirm the diagnosis in infants.

Colonic dysfunction of prematurity, or *small left colon syndrome*, produces a functional mechanical obstruction that mimics Hirschsprung disease. Small left colon syndrome can be related to extreme prematurity, maternal diabetes, prenatal maternal medications for eclampsia (magnesium sulfate), hypothyroidism, or maternal narcotic use. Small left colon syndrome is a diagnosis of exclusion because its barium contrast appearance resembles Hirschsprung

disease. Surgically, a temporary colostomy is indicated only for failure to respond to careful, small-volume, saline enema therapy or in the presence of signs of peritonitis or intestinal perforation. The prognosis for uncomplicated cases is excellent.

In the infant or toddler, accidental and inflicted blunt injury to the abdomen can result in early obstruction both from bowel wall edema and from a hematoma. A full-thickness bowel wall injury will often produce late sequelae such as an intestinal leak, which initially produces a normal or equivocal examination resulting in a delay in diagnosis. The diagnosis of acute bowel wall trauma requires a high index of suspicion and often thorough and repeated radiologic evaluations.

Infants and toddlers also are at risk for accidental ingestion of objects. These are often radiopaque and will be readily apparent on a plain film. If the object is able to pass through the pylorus, it is unlikely to cause a significant bowel obstruction. However, 2 important exceptions exist. Water-absorbing silicone or polyethylene balls will expand over time, resulting in a complete obstruction and potentially even perforation depending on size. A careful history must be taken and surgical consultation obtained if these objects were ingested. The second exception involves the ingestion of multiple magnets. These magnets may attract one another through 2 different loops of bowel. This can lead to pressure necrosis resulting in fistulization or frank perforation of multiple segments of bowel. In certain studies, the rate of peritonitis approached 50% in this situation; thus, again, surgical consultation is warranted if the child's history reveals such ingestions.

## MANAGEMENT

### Medical Management

A child who has GIO requires gastric decompression to prevent continued bowel distention, vomiting, and possibly aspiration. Intravenous fluid therapy is required immediately to replace third-space (ie, intraluminal and intraperitoneal) fluid loss. When replacing the fluid deficit, the pediatrician must remember that luminal GIO losses are high in electrolyte content, requiring administration of higher than maintenance concentrations of sodium, chloride, and potassium. Therefore, solutions such as lactated Ringer's solution are needed to provide appropriate replacement. A urinalysis, with catheterization if necessary, and a complete blood count and blood chemistry studies should be performed. Because almost all children who have GIO require emergency or semiurgent surgery, they must be well prepared for anesthesia and the surgical procedure. This approach requires correcting fluid and electrolyte, hematologic, and metabolic imbalances before surgery. Such corrective measures should begin before extensive diagnostic radiologic studies are undertaken. Medical causes of failure to pass meconium that require nonsurgical therapy include hypothyroidism, hypercalcemia, hypokalemia, sepsis, and congestive heart failure.

### Surgical Management

The type of surgical procedure performed and the child's postoperative course and prognosis (see Table 257-1) depend on the type of lesion causing the GIO.

### Esophageal Obstructions

Esophageal atresia with associated tracheoesophageal fistula constitutes a relative emergency requiring either primary repair or a staged procedure with an initial gastrostomy for gastric decompression and prevention of aspiration. Subsequent definitive repair, including a division of the fistula and anastomosis of the esophageal ends, is carried out after treatment of any existing underlying pneumonic process. Occasionally, the gastrostomy and definitive repair are performed simultaneously, and, in selected children, the esophageal repair is performed without gastrostomy. Complications of the definitive procedure include esophageal leaks, infection, and strictures. Anomalies, particularly of the cardiovascular system, as well as imperforate anus, duodenal atresia, and intestinal malrotation, are associated problems in as many as 50% of cases. Children who have uncomplicated atresia and tracheoesophageal fistula have low morbidity and negligible mortality. However, associated cardiovascular anomalies and very low birth weight lead to a mortality rate as high as 70%. Late complications of atresia and tracheoesophageal fistula include congenital hypertrophic pyloric stenosis and chronic gastroesophageal reflux with reactive airway symptoms.

### Gastric Obstructions

Gastric volvulus is usually an acute problem that requires an immediate surgical gastropexy to prevent ischemia and necrosis and a temporary gastrostomy tube for fixation and decompression. If no gastric necrosis is found, then recovery is usually uneventful. Gastric necrosis with resulting peritonitis results in high morbidity and mortality. A gastric antral web is difficult to diagnose and often requires repeated diagnostic studies, but it is not a critical problem. Surgical therapy consists of simple incision of the web and performance of a modified pyloroplasty, resulting in few postoperative complications.

Hypertrophic pyloric stenosis requires surgical therapy after adequate correction of the associated, potentially life-threatening dehydration, hypochloremic alkalosis, and hypokalemia. The procedure is a muscle-splitting pyloromyotomy, leaving the mucosa intact. The procedure can be performed laparoscopically or through a right upper quadrant or supraumbilical incision with similar operative times, complications, and costs. Acute complications are unusual, with the child resuming postoperative feedings without sequelae within 8 to 24 hours, sometimes as early as in the immediate postoperative period in the recovery room. Chronic complications such as stricture related to intraoperative mucosal perforations and adhesions are rare.

### Duodenal Obstructions

Duodenal atresia, stenosis, and annular pancreas constitute semi-urgent problems unless accompanied by

an associated volvulus, which demands immediate abdominal exploration. Surgical therapy consists of bypassing the obstructed area by means of a duodeno-duodenostomy, a duodenojejunostomy, or a gastrojejunostomy. Moderate feeding problems necessitating a longer hospitalization may be encountered, particularly when a gastrojejunostomy is performed. The prognosis is good; however, with associated congenital cardiac problems, mortality can be as high as 50%. Duodenal atresia is associated with Down syndrome (trisomy 21) in as many as 10% of cases. Growth and development are normal in children who have uncomplicated and isolated duodenal obstructions. Duodenal and other intestinal duplication cysts are treated if possible with complete excision. At the least, excision of the mucosal lining should be performed, given that cysts are associated with a late malignant transformation.

### **Jejunal and Ileal Obstructions**

Jejunal and ileal atresia are also semi-urgent conditions unless they are associated with a volvulus. Surgical treatment involves excision of the atretic bowel and primary anastomosis of the dilated proximal and the narrowed distal segments. When multiple atretic segments of bowel, or small bowel atresias associated with the absence of the superior mesenteric artery, are present, the overall intestinal length and, therefore, the absorptive surface may be greatly reduced. Total parenteral nutrition is commonly required after surgery. Overall survival and prognosis are good unless the atresia is complicated by cystic fibrosis or the remaining small intestine is too short for adequate absorption.

Malrotation with a complicating volvulus is the most critical diagnosis in any child suspected of having GIO. The twisted bowel mesentery may lead to ischemia and bowel necrosis within 4 to 6 hours after the onset of symptoms. Untreated volvulus has a high acute mortality rate because of associated metabolic imbalance and sepsis. Even after successful surgical resection of the involved necrotic bowel, high long-term morbidity can be expected. The entire embryonically derived midgut may have to be resected, leading to reduced intestinal absorption of nutrients and the so-called *short-gut syndrome*. Thus, early diagnosis, rapid correction of fluid and electrolyte imbalances, and surgical reduction of the mesenteric torsion with or without resection of potentially necrotic bowel are imperative. Proximal and distal segments of involved intestine that seem ischemic, but may be viable, should be retained by creating abdominal enterostomas in lieu of extensive initial intestinal resection followed by a second-look operation performed in 24 hours. Postoperative complications include marked fluid and electrolyte disturbances, local and systemic infections, and malnutrition. Long-term parenteral nutrition, dietary adjustments, and repeated surgical procedures should be expected. Survival with a reasonable quality of life can be expected if the remaining viable small bowel is 30 cm or longer. Morbidity is lessened when the ileocecal valve remains intact. Long-term hospitalization and prolonged nutritional support through total parenteral nutrition are usually required.

As noted previously, meconium ileus may respond to water-soluble contrast enemas; however, evidence of an accompanying intestinal perforation or failure of a carefully managed water-soluble contrast enema necessitates surgical therapy. Cystic fibrosis, which is almost always present as an underlying disease, complicates the child's postoperative respiratory and nutritional status. Administration of cleansing solutions such as *N*-acetylcysteine by means of an enterotomy usually frees the intestinal lumen of the inspissated material. Associated atretic or necrotic intestinal segments are excised, and primary anastomoses are performed. Enterostomas are created for postoperative lavage of massively impacted meconium or in instances in which the viability of the remaining bowel segments is in question. A stoma may also be needed to protect an anastomosis. A transabdominal T tube may be left intraluminally to allow decompression and irrigation, and the appendix may be used as a conduit. The surgical survival is good; however, the morbidity is high, and the ultimate prognosis is related to the severity of the other manifestations of cystic fibrosis.

### **Colonic and Rectal Obstructions**

An intussusception uncomplicated by a lead point (ie, a Meckel diverticulum, a polyp, or a malignancy) can be successfully reduced hydrostatically or by air in up to 90% of appropriately selected children. Recurrences after air-hydrostatic reduction range from 5% to 7%. Surgical intervention is required if evidence of compromised bowel is found, such as a free perforation or peritoneal irritation, and in failures of air-hydrostatic reduction. Successful reduction requires retrograde reflux of contrast media or air into the terminal ileum. Most children who have intussusceptions that are reduced intraoperatively do well postoperatively, with a low 2% to 5% recurrence rate. Bowel resection is required when an intraoperatively recognized pathologic lead point is present or when an ischemic complication is found. Early diagnosis and treatment of intussusception reduce morbidity and mortality.

Rectal atresia and imperforate anus require diagnosis, initial therapy, and colostomy within 24 hours. Very low perineal lesions (anterior displaced anus and fourchet fistula) can be treated with initial dilations only. Definitive therapy, which includes a pull-through procedure and anoplasty, is performed when the infant is 2 to 3 months of age. If the lesion is not associated with any other congenital anomalies, then survival is good. The physician should look for other anomalies, particularly those of the genitourinary tract (rectovaginal and rectovesicular fistulas, lower urinary tract obstructions with megacystis, hydroureter, and hydronephrosis). Future stool continence is related directly to the severity of the deformity, which is influenced by the degree of normal embryologic descent of the colon through the levator muscle. Definitive surgery for high lesions, in which colon descent is limited to a position above the levator muscle, results in daytime stool continence in approximately 60% of patients. The overall continence rate for high lesions is 10% to 20%. Repair of low lesions, in which

the colon has descended below the levator muscle, results in an overall stool continence rate of at least 80% to 90%.

Surgical therapy for congenital aganglionosis of the colon (Hirschsprung disease) can include creating a colostomy by using a segment of proximal ganglionic colon, followed in 6 months to 1 year by excision of the affected aganglionic segment and anastomosis of the normally innervated (ganglionic) bowel to the anus (the pull-through procedure). Many children respond preoperatively to regular rectal stimulation and irrigations to evacuate the colon. This measure allows performance of a primary pull-through procedure during the immediate newborn period and up to several months of age and the avoidance of a colostomy. Infant morbidity and mortality rates are high when the disease is complicated by enterocolitis; however, patients who have no such complications usually do well, with good anal continence, growth, and development.

### Minimally Invasive Surgery

The availability of minimally invasive techniques and instruments for infants and toddlers has allowed many procedures such as pyloromyotomy, fundoplication, and endorectal pull-throughs to be performed laparoscopically. Obstructions from adhesions, inflammation (inflammatory bowel disease, appendicitis, and Meckel diverticulitis), and intussusception can be successfully treated with minimally invasive techniques by the skilled laparoscopist. However, procedures such as pyloromyotomy may be performed with a modified open technique, which is less expensive and has equally acceptable cosmetic results. In addition, the use of the minimally invasive technique for the Ladd procedure may be less effective than the original open Ladd procedure, which causes desired adhesion formation that will result in natural fixation of the intestine to prevent future volvulus. As smaller-sized instrumentation has improved and surgeons gain more experience, the list of procedures that can be performed laparoscopically continues to grow.

### Fetal Surgery

Fetal surgery is an alternative in the treatment of some congenital anomalies. Given the risk to the mother from invasive prenatal procedures, the death of the fetus or newborn without in utero treatment has to be almost certain for fetal surgery to be considered. This assumption also applies to endoscopic fetal procedures. Currently, open or endoscopic fetal surgery is performed for congenital cystic adenomatoid malformation, fetal sacrococcygeal teratoma, congenital diaphragmatic hernia, and obstructive uropathy that meet the previously mentioned criteria. None of the prenatal GIO diagnoses or their causes pose an immediate threat to the fetus or the mother, with overall combined mortality rates of less than 5%. The benefits to the baby do not outweigh the risk to the mother; therefore, these lesions are not appropriate for prenatal interventional therapy.

*The authors thank Dr Sunny Pitt for assistance with radiologic images.*

### WHEN TO REFER

- All patients with suspected and confirmed intestinal obstruction should be referred to pediatric surgery.

### WHEN TO ADMIT

- All patients with intestinal obstruction should be admitted.

## Chapter 258 GIARDIASIS

Craig M. Wilson, MD

### ETIOLOGY

A *Giardia*-like organism associated with gastrointestinal symptoms was described by Dutch microscopist Anton van Leeuwenhoek in 1681, but only in the past few decades has the true pathogenicity of this flagellate protozoan been recognized. *Giardia intestinalis* (also known as *Giardia lamblia* and *Giardia duodenalis*) is one of the most common intestinal parasites in the United States.

A large sucking disk, which the parasite uses to attach to the intestinal mucosa, occupies most of the flat ventral surface. Attachment is regulated by contractile proteins, including actin and myosin, which alter the structure of the disk. The mechanism by which the organism evades degradation in the intestinal lumen is not clear. The motile trophozoites divide by longitudinal binary fission in the upper small bowel and then encyst as they pass into the colon. Trophozoites are usually seen only in the stool when diarrhea is present. Cysts, the more common form seen in stool specimens, are 9 to 12  $\mu\text{m}$  long. Recently formed cysts have 2 nuclei; mature cysts have 4, but cysts are generally infectious on emergence in stool (Figure 258-1). The oocysts are stable for weeks to months in the environment.

**Figure 258-1** *Giardia* organisms. The trophozoite (left) is 12 to 15  $\mu\text{m}$  long and has 4 pairs of flagella and 2 prominent nuclei. This form is not commonly seen in stools. Cysts (right) are 9 to 12  $\mu\text{m}$  long and may have 2 to 4 nuclei.

## EPIDEMIOLOGIC MECHANISM

*G. intestinalis* is one of the most commonly identified pathogens in waterborne diarrheal disease in the United States, where the organism is holoendemic. Infections are seasonal, with higher rates in late summer and early fall. In the United States, rates are highest among children younger than 5 years. Many large common-source outbreaks have been traced to contaminated drinking water. Epidemiologic studies have attributed these epidemics to cross-contamination of municipal drinking water supplies that have sewage, defective or deficient filtration facilities, and reliance on chlorination as the principal method of water disinfection. In mountainous regions, where the prevalence of disease appears to be higher, consumption of surface water is the principal problem. Although zoonotic infections have been documented, molecular epidemiologic studies suggest they may actually be quite rare. As suggested by the occurrence of epidemic giardiasis despite chlorination of municipal water supplies, routine chlorination may not be adequate for killing *G. intestinalis*. The level of chlorine necessary to kill cysts depends on many other factors, including pH, contact time, turbidity, and temperature. Thus, an adequate water purification system for clearing *G. intestinalis* should include filtration, sedimentation, and flocculation systems. Halogen-based, small-quantity disinfection methods are also affected by water clarity and temperature.

Because cysts may be shed in abundance in the stool, not surprisingly, *G. intestinalis* may be transmitted by the fecal–oral route. This route is undoubtedly the main route of spread in families, in institutions, and in child care centers. With intensive exposure to stool, as in child care centers caring for infants in diapers, giardiasis may quickly become hyperendemic. Foodborne giardiasis has been reported, but the implicated food probably was contaminated during preparation.

## PATHOGENESIS

Studies in human volunteers have demonstrated the high infectivity of *G. intestinalis* cysts. Although 1 cyst rarely was infectious, infection occurred in virtually all volunteers receiving 100 to 1 million cysts orally and in 36% of those exposed to 10 to 25 cysts. Molecular-based techniques suggest that *G. intestinalis* assemblages A and B are the predominant species infecting humans and that multiple other genotypes and species infect other hosts.

Many mechanisms have been postulated for the diarrhea and malabsorption caused by *G. intestinalis*. In all likelihood, the process is multifactorial, with the severity of symptoms dependent on the degree of focal small bowel injury. Infection is associated with injury to the mucosal brush border, with disruption of disaccharidase activity and transport mechanisms. A basal membrane and intraepithelial layer inflammatory cell infiltrate have been found, and evidence exists of an increased enterocyte turnover in the murine model. In either case, less efficient villus function would be expected. In the extreme, the microvilli atrophy results in the severe malabsorptive diarrhea, which is a major complication of giardiasis. Recent studies suggest that parasite products play a role in the pathophysiologic mechanism of this infection. Evidence also has been found that some *Giardia* strains produce more severe symptoms in humans than they do in other species, and differences in phenotype and genotype have been correlated with virulence in experimental models of infection.

Host defense mechanisms appear to be relatively inefficient, given the small number of organisms required to initiate infection and the frequency of relapse and reinfection. However, intraluminal secretory antibody response, nonspecific inflammatory responses at the level of the mucosa, and antibody-dependent cell-mediated cytotoxicity appear to be important in limiting the severity of disease. The role of antibody and antibody-dependent cell-mediated cytotoxicity in containing giardiasis is supported by the increased incidence and severity of disease in patients who have immunoglobulin deficiencies. Underlying immunoglobulin A deficiency and both X-linked and common variable hypogammaglobulinemia have been associated with severe or prolonged infection.

*G. intestinalis* should be considered in the evaluation of diarrhea or malabsorption in patients who have human immunodeficiency virus (HIV) infection. The role and extent of *G. intestinalis* infections in children who have HIV infection have not been established. Of course, diarrhea in patients who have acquired immunodeficiency syndrome is often multifactorial, and treatment of documented giardiasis may not result in clinical improvement if other pathogens still are present (see Chapter 268, Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome).

## CLINICAL MANIFESTATIONS

Based on experimental studies and point-source outbreak observational data, the incubation period of giardiasis is 7 to 14 days. Most patients infected by *G. intestinalis* probably remain asymptomatic, although they do shed cysts in their feces and are infectious.

Children are more likely than adults to have symptomatic disease.

The principal symptoms of giardiasis are gastrointestinal. Diarrhea, abdominal cramps, and nausea are reported most often. Vomiting, malodorous stools, flatulence, bloating, anorexia, and even constipation are noted less frequently. Because the colon and rectum are not involved, tenesmus should suggest another diagnosis. Blood almost never is found in the stool, and the presence of mucus is unusual. Gastrointestinal symptoms generally last 7 to 10 days, although a more protracted course is common. Because of the disaccharidase deficiency that accompanies severe infections, some patients complain of milk intolerance, which may last for weeks.

Constitutional symptoms are not prominent in giardiasis, but up to 25% of patients experience fatigue, headache, or a low-grade fever. Extraintestinal syndromes, such as urticaria, erythema multiforme, and arthralgia, have occurred, but very rarely, in association with giardiasis.

Some patients, particularly children, develop chronic diarrhea, frank malabsorption, weight loss, malnutrition, and growth restriction. Thus, giardiasis must be considered in the differential diagnosis of failure to thrive. Occasionally, giardiasis may be misdiagnosed as sprue, food allergy, or psychogenic abdominal pain, and its protean clinical manifestations may mimic a wide variety of gastrointestinal disturbances. Malabsorption leading to an iron deficiency anemia also has been reported with *G intestinalis*.

The physical examination is generally unremarkable unless secondary malnutrition has developed.

## LABORATORY EVALUATION

The clinical laboratory diagnosis of *G duodenalis* has predominantly changed from a microscopic examination of stool to either heat-stable antigen detection in stool or detection of parasites by fluorescence. These tests are quite often combined for simultaneous detection of *Cryptosporidium* species. Overall, these tests compare well with standard microscopic procedures and are in most cases more sensitive, although multiple samples may still be needed for optimal detection.

A few patients require additional measures to have the pathogen detected. Examining the duodenal contents provides the optimal yield, and this examination can be performed either by direct duodenal aspiration or by using the Entero Test. In rare patients with chronic symptoms in whom the diagnosis must be excluded, biopsy of the small bowel should be done. Several sections of the biopsy specimen stained with Giemsa stain may have to be examined to find the parasite; *Giardia* organisms are detected more easily in Giemsa-stained mucosal impression smears.

Serologic tests are valuable in epidemiologic studies but are of little use diagnostically. Upper gastrointestinal radiographs may reveal mild dilation of the small bowel, edema of the mucosa, segmentation of barium, and either increased or decreased transit times; however, these changes are nonspecific. The sedimentation rate is normal, and no eosinophilia is found because the parasite is noninvasive. Biochemical evidence of malabsorption may be found, including

disaccharidase deficiency, abnormal absorption of D-xylose and fat, and a deficiency of folic acid.

## THERAPY

Most authorities agree that giardiasis should be treated when recognized, even if the patient is asymptomatic, because carriers of the parasite are potential transmitters of disease and may have subclinical malabsorption. However, physicians may elect not to treat asymptomatic patients, particularly if re-exposure to *G intestinalis* seems unavoidable in some hyperendemic settings.

Metronidazole has been used widely to treat giardiasis in adults and children because it is well tolerated (except for the mild metallic aftertaste), has a very low incidence of serious side effects, and has an acceptable cure rate. Alcohol ingestion, including in concurrent medications, should be avoided with metronidazole because of disulfiram-like reactions. Of note, giardiasis is not an approved indication for metronidazole in the United States. Tinidazole, a nitroimidazole similar to metronidazole, which has been used extensively in a single-dose regimen outside of the United States, is approved for the treatment of giardiasis in children 3 years and older. Both metronidazole and tinidazole can readily be formulated as suspensions.

Furazolidone has the distinct advantages of having a pleasant taste and being available in a pediatric suspension. Side effects, which have been minimal in children, include mild gastrointestinal distress, hypersensitivity reactions, hemolysis in individuals who have glucose-6-phosphate dehydrogenase deficiency, brown discoloration of the urine, and disulfiram-like reactions. Furazolidone is contraindicated with monoamine oxidase inhibitors. The efficacy in children has been as high as 92%, which is comparable if not superior to cure rates seen with alternative agents.

Nitazoxanide is an approved antiparasitic agent with specific indications for the treatment of cryptosporidiosis and giardiasis in children. Cure rates in small, randomized trials were comparable to those of standard agents for giardiasis, and side-effect rates appear comparable to placebo. On rare occasions, yellow sclera is noted, which clears with discontinuation of the drug. Nitazoxanide is the most costly of the agents discussed here.

Albendazole has been reported to be as effective as metronidazole in a limited number of studies in children. Albendazole has the advantage of being active against a broad range of intestinal parasites, including helminths, if this is a consideration. Paromomycin, a nonabsorbable aminoglycoside, has been used to treat giardiasis in pregnancy, but data regarding its efficacy are limited. Quinacrine, a once commonly used therapy, is not commercially available in the United States but can be obtained if needed through compounding pharmacies, such as Panorama Compounding Pharmacy (6744 Balboa Blvd, Van Nuys, CA 91406 [800-247-9767]) or Medical Center Pharmacy (New Haven, CT [203-688-6816]). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, [www.pccarx.com](http://www.pccarx.com)). Relapse is possible after using any of

these regimens. If this occurs, re-treatment with the same agent or an alternative drug is often successful. No well-documented evidence exists for actual drug resistance in *Giardia* on an individual clinical case level. In vitro sensitivity has shown variations but is assay and inoculum dependent. For cases of severe or recalcitrant infections, prolonged or combination therapy may be necessary.

## PREVENTION

Because giardiasis is so prevalent, total prevention of transmission is virtually impossible. When the disease is known to be present in a household, institution, or child care center, good hand washing is essential to limit spread by the fecal–oral route. Personal hygiene is especially important when infants in diapers are affected. When an outbreak is thought to occur in child care centers that have infants in diapers, the local health department should be contacted, and an epidemiologic investigation should be undertaken to identify and treat all symptomatic children, child care workers, and family members infected with *Giardia*.

As already noted, prevention of waterborne giardiasis is contingent on adequate water purification, including filtration, sedimentation, and flocculation in addition to chlorination. Tourists in endemic areas should avoid drinking tap water. Campers should not rely on chlorination tablets, which are ineffective against *Giardia* cysts. Boiling for at least 2 minutes, even at high altitudes, or filtration (pore size under 1 µm or with a filter rated for cyst removal) are satisfactory means for preparing drinking water free of *G. intestinalis*. General guidance for water filter specifications and recommendations are available at [www.cdc.gov/travel/foodwater.htm](http://www.cdc.gov/travel/foodwater.htm).

## Chapter 259

# GLUTEN-SENSITIVE ENTEROPATHY (CELIAC SPRUE)

Anca M. Safta, MD; John A. Kerner Jr, MD

Celiac disease (CD), also known as celiac sprue or gluten-sensitive enteropathy (GSE), is a condition characterized by clinical features of malabsorption and pathologic changes in the jejunal mucosa, both of which improve when gluten is removed from the diet and recur when it is reintroduced. CD is the second most common cause of malabsorption in children, the most common being cystic fibrosis. Even though CD is characterized by malabsorption, the disease is extremely protean in its manifestations and many children with CD may not have features of overt malabsorption.

The classic clinical description of CD was first provided in 1888. In 1950, the association between the ingestion of gluten and CD was noted. During World War II, when grain products were in short supply, the incidence of CD was markedly reduced, and children who had the disease improved. After the war, when cereal grain again became plentiful, the incidence of CD quickly returned to prewar levels. In 1954, the first accurate description of intestinal lesions in patients with CD was provided by studying surgical biopsy material. Not until 1968 was the discovery made that adult nontropical sprue and CD in childhood were the same disease.

## INCIDENCE

The precise incidence of CD is unknown because many patients have asymptomatic disease. Screening with serologic markers has increased the estimates of prevalence of CD in different areas. CD has been identified in Hispanic, Indian, Chinese, Sudanese, African Caribbean, and Middle Eastern people. Although the disorder was once thought to be more common in Europe than in the United States, such is no longer the case; in England the prevalence is 1 in 87, in Finland 1 in 99, in Spain 1 in 389, in Iran 1 in 166, in the Sahara 1 in 18, and in the United States 1 in 133. The worldwide average prevalence for CD is estimated to be 1 in 266.

In children, the average age at the time of diagnosis is under 24 months. Diagnosis occurs sooner in infants who are fed products containing gluten at an early age and have not been breastfed. The clinical incidence declines markedly after age 2 years, and diagnosing CD in a teenager is even less common. In

**Figure 259-1** Normal jejunal mucosa. Villi are tall, crypts are relatively short, and the crypt-villus ratio is approximately 1:4. Epithelial cells are columnar, with basally oriented nuclei. Some lymphocytes and plasma cells are found in the lamina propria.

adults, CD often clinically develops after a precipitating illness, such as infectious diarrhea, or after a surgical procedure, such as gastrectomy, with a peak between the third and fifth decades of life. As with other autoimmune diseases, CD is more prevalent in females with a female-to-male ratio of approximately 2–3:1; however, individuals diagnosed over the age of 60 years are more likely to be male.

Clinical diagnosis of CD has become much more common, which has led to increased incidence. This increase results from the advent of routine upper endoscopy in evaluating patients with abdominal pain and finding a flat villus lesion during routine small-bowel biopsy, and from the use of serologic markers in the routine screening of family members and screening for associated diseases.

The concept of the “celiac iceberg” is used to illustrate the fact that despite the high prevalence of CD, there remains a large number of undiagnosed patients. The tip of the iceberg represents only 3% to 5% of those diagnosed with CD and is comprised of symptomatic individuals with mucosal injury. The silent CD is the next level of the iceberg, and includes patients with mucosal injury who are asymptomatic. These are new patients picked up through family history and other associated disease screening. The largest portion of the iceberg is the bottom, the so-called latent CD. These are patients with the appropriate genetic makeup and autoimmune markers, but with no mucosal damage. Given the right environmental triggers, these patients can develop into full-blown symptomatic CD.

### **PATHOLOGIC FEATURES**

CD primarily affects the mucosa of the small intestine. The submucosa, muscularis, and serosa are not involved. The mucosal lesion of the small intestine in

CD varies in severity and extent; lesions in the jejunum are generally more severe than those in the ileum. This variability may explain the differences in the degree of malabsorption observed in some patients; those in whom more intestinal area is involved presumably have a greater degree of malabsorption. This difference in the distribution of the lesion suggests that the proximal intestine has greater exposure to undigested gluten than the distal intestine, because no greater sensitivity to gluten is found in the proximal mucosa than in the distal mucosa.

Among patients with active CD, surface epithelial-cell damage occurs, and more cells migrate from the crypt to the villus region. Compensatory crypt hypertrophy occurs, with a marked increase in mitotic activity, and gradual villus flattening develops (Figure 259-1 and Figure 259-2). The surface epithelial cells demonstrate a loss of the basal nuclei polarity and become more cuboidal. Many intraepithelial lymphocytes are noted, and the lamina propria shows a marked increase in plasma cells and lymphocytes. This flat villus lesion is not pathognomonic of CD; it may be seen in many other diseases. With the introduction of the flexible endoscope, which permits focused biopsy rather than blind suction biopsy, investigators have found nonspecific antral gastritis in 10% of patients who have GSE, which implies the presence of some gastric sensitivity. In addition, occult CD should be suspected in patients with chronic diarrhea and evidence of biopsy-proven lymphocytic or collagenous colitis.

### **PATHOGENESIS**

CD is a genetic disease, although the complete mode of inheritance remains to be fully elucidated. Several genes seem to be involved, with the most consistent

**Figure 259-2** Jejunal mucosa in gluten-sensitive enteropathy (celiac sprue). Mucosa is flat, villi are absent, and crypts are deep. Epithelial cells are cuboidal, and nuclei are not basally oriented. Increased numbers of mitoses in the crypts is found. Inflammatory cells, especially plasma cells and lymphocytes, are markedly increased ( $\times 160$ ).

genetic component being the presence of *HLA-DQ2* or *HLA-DQ8* genes. These genes are necessary to develop disease although not sufficient by themselves; therefore, patients who lack this genetic background cannot have GSE. The *HLA-DQ2* allele combination is found in 90% to 95% of patients with GSE (however, 20% to 30% of the normal population also has this combination); the remaining 5% to 10% of patients are *HLA-DQ8* positive. The disorder requires both the genetic background and exposure to gluten, which is present in wheat, barley, and rye.

Two mechanisms of disease have been proposed. First, CD may result from the lack of a specific enzyme, a dipeptidase, which results in accumulation of toxic gluten peptides, such as the newly identified protein-rich peptide 33-mer, found in gluten. This peptide may be the primary initiator of the inflammatory response in susceptible individuals. 33-mer is the antigen that reacts with tissue transglutaminase and induces the gut-derived human T-cell lines. Second, gluten toxicity may be mediated through immunologic aberrations associated with genetically determined cell-surface markers.

Various immunologic abnormalities have been described in CD. First, increased levels of serum immunoglobulin A (IgA) and lowered levels of serum IgM are abnormalities that are reversed by a gluten-free diet (GFD). Second, intestinal mucosal immunoglobulin synthesis, notably IgA and IgM, is markedly increased in patients who have active CD. This synthesis returns to normal with remission. Fifty percent of the increased IgA is associated with specific anti-gluten antibody. Third, patients with active CD respond to corticosteroid treatment. Fourth, duodenal mucosa and peripheral lymphocyte transformation in response to gluten has been described in patients with CD.

## CLINICAL MANIFESTATIONS

Many patients with CD present with protean manifestations. However, a patient with an advanced case of CD is typically an irritable, anorectic child with chronic diarrhea, failure to thrive, a potbelly, and muscle wasting, especially of the buttocks and proximal limbs. These children are usually easy to diagnose (Figure 259-3). Nonetheless, many patients exhibit the disorder atypically. Box 259-1 lists atypical features of patients with CD. Such features are usually related to selective malabsorption of various nutrients. Therefore, patients with CD may have rickets, osteoporosis with bone pain, or pathologic fractures. Also seen are bleeding disorders that result from vitamin K deficiency, iron-deficiency anemia, and megaloblastic anemia, which is usually the result of folate deficiency. Vitamin B<sub>12</sub> deficiency is rare and usually indicates severe disease that extends to the terminal ileum. Constipation, rectal prolapse, clubbing of the fingernails, edema, and vomiting have also been reported. CD should always be considered in patients with specific nutritional defects who do not respond to nutrient replacement therapy.

Celiac crisis is a rare, life-threatening condition characterized by massive diarrhea, severe electrolyte imbalance, dehydration, or shock that needs to be recognized promptly. It can be triggered by severe malnutrition, an infectious process, poor compliance with the GFD, bacterial overgrowth caused by dysmotility, or hypoproteinemia. The patient needs to be admitted into the intensive care unit for further stabilization of electrolytes and fluids. Once the fluid shifts have stabilized, the goal is to start parenteral nutrition with total gut rest.

**Figure 259-3** Classic profile of patient with gluten-sensitive enteropathy (celiac sprue): potbelly, thin buttocks, and proximal muscle wasting.

#### **BOX 259-1 Atypical Manifestations of Gluten-Sensitive Enteropathy**

- Growth failure (without gastrointestinal symptoms)
- Anemia
- Iron deficiency
- Folate deficiency
- Vitamin B<sub>12</sub> deficiency (rare)
- Rickets, osteoporosis, pathologic features
- Bleeding disorders
- Edema
- Constipation
- Vomiting
- Recurrent abdominal pain

Slowly, introduction of a GFD with oral supplementation of iron, folic acid, vitamin D, and calcium should be attempted. These patients might require prolonged total parenteral nutrition.

Acutely, patients may require intravenous steroids to be stabilized.

#### **BOX 259-2 Common Causes of Flat Villus Lesion**

- Food sensitivity
- Gluten-sensitive enteropathy
- Cow's milk protein allergy
- Soy protein allergy
- Eosinophilic gastroenteritis
- Infection
- Viruses (rotavirus)
- Bacteria (*Escherichia coli*)
- Parasite (*Giardia lamblia*)
- Fungi (*Candida albicans*)
- Malnutrition (kwashiorkor, not marasmus)
- Tropical sprue
- Immunodeficiency disorders (most notably AIDS)
- Familial enteropathy
- Lymphoma
- Crohn disease
- Whipple disease

### **DIFFERENTIAL DIAGNOSIS**

In children younger than 18 months of age, flat villus lesions can have many causes besides GSE. Many gastrointestinal insults can damage surface epithelial cells, resulting in increased epithelial cell turnover, crypt hypertrophy, abnormal surface epithelial cells, and eventual villus flattening. Other causes of flat villus lesions are listed in Box 259-2.

For a definitive diagnosis of CD, the following criteria must be met: demonstration of clinical malabsorption and abnormal intestinal lesions; clinical and histologic response to gluten withdrawal; and subsequent gluten challenge that may exacerbate clinical symptoms, but that always produces abnormal intestinal histologic findings. The diagnosis must be made with certainty because CD means lifelong gluten restriction, and untreated patients are at a higher risk for developing gastrointestinal cancer in late adulthood.

#### **Serologic Markers**

Serologic markers emerged as a diagnostic tool and screening test for CD during the early 1980s. These serologic markers include anti-gliadin (AGA), anti-deaminated gliadin peptide antibody (anti-dGp), anti-reticulon antibody, anti-endomysial (anti-EMA) antibody, and anti-serum tissue transglutaminase (tTG) antibody. These serologic tests are used for symptomatic patients who need a biopsy; for screening of asymptomatic patients at risk, such as first- and second-degree relatives and those with other disorders associated with a high prevalence of CD; as supportive evidence for the disease; and to follow dietary compliance.

The first marker used for celiac serology screening was AGA antibodies. AGA antibodies are formed as a response to gliadin found in wheat, rye, and barley.

**Table 259-1** Celiac Serology

TEST	SENSITIVITY (REPORTED RANGE)(%)	SPECIFICITY (REPORTED RANGE)(%)	POSITIVE PREDICTIVE VALUE (%), PRETEST PROBABILITY OF 5%	NEGATIVE PREDICTIVE VALUE (%), PRETEST PROBABILITY OF 5%
IgA AGA	85 (57–100)	90 (47–94)	18	99
IgG AGA	85 (42–100)	80 (50–94)	31	99
EMA	95 (86–100)	99 (97–100)	83	99
IgA anti-tTG	98 (78–100)	98 (90–100)	72	99
IgG anti-tTG	70 (45–95)	95 (94–100)	42	99
IgA anti-DGP	88 (74–100)	95 (90–99)	44	99
IgG anti-DGP	80 (63–95)	98 (90–99)	68	99
IgA/IgG anti-DGP	97 (75–99)	95 (87–100)	51	99

AGA, anti-gliadin antibody; DGP, deamidated gliadin peptide; EMA, endomysial antibody; tTG, tissue transglutaminase.

From Leffler DA, Schuppan D. Update on serologic testing in celiac disease. *Am J Gastroenterol*. 2010;105:2520–2524. Reprinted with permission from Nature Publishing Group.

AGA IgA is more specific when compared to the AGA IgG (82%–95% vs 73%–90%) but lacks in sensitivity compared to its IgG counterpart (70%–90% vs 85%–98%). However, in children under 2 years, the tTG sensitivity is only 88% compared to 95% sensitivity in the older patient, making it helpful to use a panel of both AGA and tTG antibodies in such patients.

EMAs are developed in reaction to the ongoing damage to the intestinal lining by exposure to gluten in the predisposed individual. This test is more subjective because it is operator dependent, yet it has the best specificity (100%). Its sensitivity is also superior to the AGA antibodies (85%–98%). There are a few instances in which one can use it in the celiac panel to support the need for biopsies. In diabetic patients or patients with other autoimmune disorders, this test can be used together with a test for tTG antibodies. The tTG antibodies can be elevated primarily because of the nature of the other autoimmune disorder and not necessarily as an overlap with CD. A positive EMA IgA test increases the specificity of the serologic test and the need to biopsy.

tTG is the actual antigen that the anti-EMA antibody is detecting in the Immunofluorescence antibody assay (IFA) testing. In 1997, the EMA IFA was slowly replaced with tTG antibodies because this test is easier to perform by an enzyme-linked immunosorbent assay (ELISA) that is not operator dependent. The tTG antibodies have been evaluated as being perhaps even more sensitive than EMA antibodies (90%–98% vs 85%–98%); therefore, they are suggested as a first step in the screening process. EMA (IgA) antibodies should be used as a confirmatory test when the findings of tTG antibody testing are equivocal. These IgA-dependent tests could produce a false-negative result in patients with CD who are IgA deficient. In the IgA-deficient individual, the tTG IgG should be considered.

False-positive EMA and tTG antibody tests are unusual. A small-bowel biopsy should be performed to confirm the diagnosis of CD when serologic markers are positive. tTG has high specificity, but, rarely, other immune disorders, such as type 1 diabetes mellitus (T1D), Crohn disease, ulcerative colitis, autoimmune

hepatitis, severe heart failure, arthritis, and collagen vascular disorders, will also have positive tTG antibodies. If the EMA antibody testing is positive then, most likely, CD should be considered. A false-positive EMA result in a patient with normal tissue biopsies could be caused by poor tissue sampling, because this is a patchy disease; by distal small bowel disease that can be detected if using enteroscopes or wireless video capsule endoscopy to reach further into the jejunum/ileum; or by latent disease that has not manifested itself yet.

### New Tests and Their Value

Anti-DGP antibodies are the new generation of more sensitive and specific AGA antibodies both in IgA and IgG form. Measurement of DGP antibodies can be of use to the current serologic panel in situations of equivocal EMA or TGA results. Also, in IgA-deficient states, the DGP IgG assay may be more sensitive and used together with the tTG IgG antibodies to increase the positive predictive value of the test. Because the formation of DGP antibodies depends on the existence of tTG antibodies, they are not superior and cannot replace the use of tTG antibodies. In patients with only neurologic presentation, screening should still be performed by using AGA antibodies, because they have better sensitivity. Leffler and Schuppan have summarized the reliability of all the antibody screening in one table. (See Table 259-1).

### Genetic Markers

CD has a genetic predisposition, and recently the genes involved have been described. The major histocompatibility complex (HLA) class II genes *DQ2* and *DQ8* are involved in CD, above 90% and 8%, respectively. The use of these genetic markers in the screening process is not well clarified. These tests, if negative, exclude the possibility of CD; however, positive test results in patients who are asymptomatic and have normal biopsy results present a diagnostic and management dilemma. These genes are necessary, but not sufficient, for the development of CD. Thirty percent of the population has a positive *HLA-DQ2* and might never develop CD. Genetic testing is

recommended in the following instances: (1) patients who are on a GFD for more than 3 months prior to any testing and are refusing a gluten challenge; (2) patients who have equivocal changes on the intestinal biopsy; (3) patients who belong to high-risk groups with other autoimmune disorders and who want to avoid long-term serologic screening (one exception are those with T1D, because they can share the same genetic background); (4) in the screening process of family members who do not want periodic serologic screening.

### Family Screening

Because GSE is often asymptomatic, screening of family members of patients with confirmed GSE should be undertaken. Approximately 20% of family members may have GSE without being aware of it. The incidence in first-degree relatives is 1 in 18 to 22; for second-degree relatives, the incidence is 1 in 24 to 39. Parents and siblings should have serum tTG antibody screening and, if necessary, serum endomysial antibodies as a confirmatory screening test. In the IgA-deficient groups, tTG-IgG and endomysial antibody-IgG serologic markers should be assessed. If these tests are positive, then small-bowel biopsies should be performed.

### Associated Diseases

Diseases associated with an increased incidence of GSE include T1D; IgA deficiency; Down, Turner, and Williams syndromes; and autoimmune thyroiditis. These patients may be assessed for GSE with serum tTG antibody testing or *HLA-DQ2* and *HLA-DQ8* genetic screening, or both.

## EVALUATION

In children who present with symptoms of malabsorption, before evaluation for CD is pursued, a sweat test should be performed to exclude cystic fibrosis, the most common cause of malabsorption in childhood. Sometimes these 2 disorders coexist. Diagnostic tests are discussed in detail in Chapter 138, Diarrhea and Steatorrhea. Screening for GFD compliance should be conducted initially every 6 months until the patient has 2 consecutive negative tests, and annual screening should be conducted thereafter. Compliance screening should be done with the initial identified positive antibody.

### Laboratory Evaluation

Anemia is common in CD and usually occurs as a result of iron, folate, or vitamin B<sub>12</sub> malabsorption. Hypoprothrombinemia may occur as a result of vitamin K malabsorption. Because protein-losing enteropathy may occur in patients with CD, serum albumin and globulin levels should be measured. Electrolyte disturbances, especially hypokalemia, are common; calcium, phosphorus, and alkaline phosphatase levels may be abnormal in patients with rickets. The radiographic findings in CD, which are nonspecific (Figure 259-4), include distended small intestine and segmented barium as a result of hypersecretion of intestinal fluid.

**Figure 259-4** Small-bowel follow-through of child with growth failure showing mild dilation of loops of small bowel, some dilation of barium distally, and mild flocculation. Duodenal biopsy revealed typical gluten-sensitive enteropathy (celiac sprue). Patient responded to a gluten-free diet.

### Intestinal Biopsy

Biopsy of the small intestine is the best way to diagnose CD. Previously, blind biopsies were performed with either the Crosby capsule or the Quinton-Rubin pediatric suction tube. Currently, biopsy specimens are routinely obtained by fiberoptic endoscopy to establish this diagnosis, and adequate tissue can be obtained by this technique. Endoscopy also permits visualization of the duodenum. Scalloping of the small intestinal valvulae of Kerckring has been described as pathognomonic for CD on endoscopy (Figure 259-5). In young infants, this appearance may be harder to visualize, but, in this patient population, edema of the duodenal mucosa is more common. Biopsies from the second portion of the duodenum showed the highest yield; however, a recent recommendation to increase the sensitivity of the test is to have duodenal bulb biopsies as well, since CD has a patchy and “proximal to distal” distribution.

In the past, authorities recommended that, after 1 or 2 years of a GFD, intestinal biopsies should be repeated to demonstrate complete recovery of the intestinal mucosa. A rechallenge with gluten was then initiated to initiate mucosal damage, which would be reassessed by intestinal biopsy. However, the recommendations for children older than 2 years of age have changed. Currently, repeat biopsy and rechallenge are not necessary if the child has become asymptomatic on a GFD. Instead, monitoring serum tTG or EMA

**Figure 259-5** Results of endoscopy showing scalloping of the small intestinal valvulae of Kerckring, a pathognomonic finding for gluten-sensitive enteropathy (celiac sprue).

antibodies (or both) is the preferred method. In contrast, children with indeterminate diagnosis should undergo another biopsy to demonstrate healing and then undergo rechallenge and another biopsy.

In patients who have normal histology and positive serology, consideration should be given to the video capsule endoscopy (VCE) to attempt to visualize the whole small bowel, because CD is a patchy disease and rarely it can present with distal distribution, making the classic diagnostic approach difficult. The VCE also should be considered in patients who are on a GFD but are symptomatic, especially those who present with alarm symptoms, such as fever, weight loss, and pain. Four endoscopic markers have been described in the pathogenesis of CD that help in making the diagnosis: scalloping, micronodularity, loss of folds, and mosaic pattern. The sensitivity of these markers has been reported from 47% to 100%, depending on the severity of the disease.

## MANAGEMENT

The treatment of CD is complete withdrawal of gluten from the diet, particularly exclusion of wheat, rye, and barley. Nutrition counseling by a qualified dietitian is an important component in the treatment of such patients. GFDs and recipes should be given to all patients or their parents. Although oats may be eaten by children with CD because oats do not contain gluten, they may be cross-contaminated with gluten during the manufacturing process.

Weeks may be required for symptoms to disappear completely after gluten is withdrawn from the diet; however, subjective improvement occurs within the first few days. In children, apathy is usually the first symptom to be alleviated, followed by progressive improvement in muscle tone, a decrease in abdominal

distention, and improvement of diarrhea. Disaccharidase activity is markedly depressed in CD; thus, a lactose-free diet is advocated during the initial 4 to 6 weeks of therapy to alleviate the diarrhea. Lactose may then be gradually reintroduced, provided that no concurrent infection, severe electrolyte imbalance, dehydration, or shock (celiac crisis) occurs.

Despite good compliance with a GFD, an estimated prevalence of refractory CD is between 7% and 30%, especially among adults. These patients are resistant to a GFD and require therapy with immune modulators. In an adult study, supplementation with pancreatic enzyme therapy has been proposed as beneficial in patients with chronic diarrhea and low fecal elastase, suggesting an exocrine pancreatic insufficiency.

Replacement iron, folic acid, vitamin K, vitamin D, and calcium should be initiated when appropriate. Compliance with a GFD can now be tracked by assessing the patient's serologic markers. An increase in tTG antibody will be observed if the patient does not comply with the diet.

The future is promising because much research is being conducted in the development of agents that can break down the gliadin and decrease the mucosal permeability, in addition to genetic engineering of safer grains and possible immunization to better tolerate or consume such grains.

## WHEN TO REFER

Referral to a gastroenterologist needs to be made based on clinical suspicion, the presence of positive serologic markers, first-degree relatives with GSE, syndromic presentations, and existence of other autoimmune disorders.

## Chapter 260 GUILLAIN-BARRÉ SYNDROME

Lalitha Sivaswamy, MD

The term Guillain-Barré syndrome (GBS) applies to a group of acquired, immune-mediated conditions affecting the peripheral nerves and nerve roots with occasional involvement of the cranial nerves. The term *acute inflammatory demyelinating polyradiculoneuropathy* (AIDP) was formerly synonymous with GBS because this was considered the primary pathology, but AIDP is now considered a subtype of GBS (see list of subtypes in Box 260-1). Other subtypes exhibit *axonal* pathology, thereby challenging the formerly held concept that GBS is an exclusively demyelinating disease.

The condition was initially described by Landry in 1859 as a cause of “ascending paralysis” and further elucidated by Guillain, Barré, and Strohl in 1916 as a polyneuritis with albuminocytologic dissociation on spinal fluid analysis. Hence, the condition could strictly

### BOX 260-1 Types of Guillain-Barré Syndrome

1. Acute inflammatory demyelinating radiculopolyneuropathy (AIDP); accounts for most cases in North America
2. Acute motor axonal neuropathy (AMAN)
3. Acute motor sensory axonal neuropathy (AMSAN)
4. Miller Fisher syndrome; can be considered a forme fruste of Guillain-Barré syndrome, and certain cases do ultimately involve the limbs and respiratory muscles
5. Polyneuritis cranialis; involves acute onset of multiple cranial nerve palsies
6. Acute sensory neuropathy
7. Acute pandysautonomia

be referred to as Landry-Barré syndrome but remains best known as GBS.

## EPIDEMIOLOGY

Guillain-Barré syndrome occurs with a frequency of about 0.5 to 1.5 in 100,000 in individuals younger than 18 years.

When children are affected, they are usually older than 3 years, with the most common age group being 4 to 8 years. The youngest patient described in the literature is a newborn, who presented at birth with generalized hypotonia.

Cases of children presenting in infancy have been described in the literature, hence physicians should entertain it as a differential diagnosis when encountering a floppy child in this age group. In the post-polio era, GBS has emerged as the most common cause of acute flaccid paralysis in childhood. Recent studies in the United States point to a slightly higher rate in the winter and spring compared with summer, reflecting the fact that GBS may follow antecedent viral respiratory infections such as influenza or influenza-like illnesses, which commonly exhibit seasonal predilection. In certain parts of Northern China and Mexico, it is more prevalent in the summer months because of its relationship with enteric pathogens. One-third of all GBS cases in such countries tend to be of the acute motor axonal neuropathy (AMAN) variety. A slight male predominance has been noted in most studies.

## ETIOLOGY AND RISK FACTORS

Guillain-Barré syndrome is an autoimmune condition and, in about two-thirds of cases, manifests as a postinfectious illness. Antecedent illnesses include chickenpox, hepatitis, cytomegalovirus, mycoplasma pneumonia, gastrointestinal illnesses, infections caused by Epstein-Barr virus, influenza-like illnesses, and urinary tract infections. The most well-documented association has been between the AMAN variant and

preceding *Campylobacter jejuni* infections. In the United States, such cases are relatively uncommon, but in certain areas of China they may account for more than 60%.

Epidemiologic studies have noted a 77 to 100 times higher risk for patients developing GBS in the 2 months following symptomatic *C. jejuni* infection compared with the general population, even in the Western world. A recent review of the world literature suggests that up to 30% of worldwide cases of GBS may be attributable to infection with *Campylobacter*.

Virologic studies using complement fixation testing noted serologic evidence of influenza infection in 3.5% of GBS patients admitted to a hospital setting in a large French cohort that primarily encompassed adults. Most patients had influenza A, and the subtypes were reflective of the prevalent epidemiologic strain. In addition, GBS has been reported following the 2009 H1N1 pandemic with D222E (H1N1) subtype of influenza.

Surgical procedures and some malignancies (particularly Hodgkin disease and some lymphomas) are temporally associated with GBS. The average time-frame between the preceding illnesses and neurologic symptoms is 1 to 3 weeks.

The administration of the A/New Jersey strain of the swine influenza vaccine in 1976 caused a sharp increase in GBS cases that year. The swine flu vaccination program was discontinued in 1977 because of this unacceptably high risk for GBS.

However, in the time period from 2006 to 2012, the administration of the seasonal influenza vaccine was followed by average attributable risk of 1 to 2 cases per 1 million doses. The risk was comparable to the 2009 H1N1 monovalent inactivated vaccine as well. Therefore, the influenza vaccine does seem to confer a very small, but possibly significant, risk for developing GBS. For physicians to assess the risk for GBS after influenza infection versus vaccination, it is worth considering that analysis of information from the United Kingdom General Practice Research Database has indicated that the relative incidence of GBS within 90 days of an influenza-like illness was 7.35, whereas after immunization it was 0.7. In summary, immunization against influenza seems to offer greater protection than risk both to society and to individuals. The Institute of Medicine has observed that “evidence is inadequate to accept or reject a causal relationship between influenza vaccine and GBS.”

Populations given the quadrivalent conjugated meningococcal vaccine demonstrated an increase of 1 additional case of GBS per 1 million individuals vaccinated.

The Centers for Disease Control and Prevention have issued guidelines with respect to these particular vaccines (see “Prevention”). Most evidence linking GBS to vaccines is temporal in nature, and causality has not been clearly established.

About half of all diagnosed cases of GBS, especially in the West, have no identifiable cause.

## **PATHOPHYSIOLOGY**

Guillain-Barré syndrome is believed to result from cross-reacting antibodies generated during a prior

infectious illness. The most common variant, AIDP, is characterized by macrophage-mediated destruction of myelin sheaths. The activated macrophages are believed to be targeted to epitopes on the myelin sheath. Pathologically, a mononuclear infiltrate is present around endoneurial blood vessels as part of the immune response to the inciting antigen. Animal models of AIDP, known as experimental allergic neuritis, are characterized by the presence of CD4<sup>+</sup> and CD8<sup>+</sup> T cells as well as macrophages around proximal nerves and nerve roots. These inflammatory cells produce a variety of proinflammatory mediators, including tumor necrosis factor- $\alpha$  and interferon- $\gamma$ , at the site. The exact antigenic target has not been clearly elucidated. This process is extensive and may involve the lower extremities, arms, trunk, nerves supplying the respiratory muscles, and select cranial nerves. The demyelination tends to occur both proximally, at the level of the nerve roots, and distally, producing the characteristic clinical features. Resting Schwann cells repair the injured segments by proliferation and laying down fresh myelin.

On the other hand, in acute motor sensory axonal neuropathy (AMSAN) and AMAN, the chief targets of immune attack are the axolemmal membranes. The outcome is variable and depends on whether this process occurs proximally or distally. The more proximally the nerve is injured, the more irreversible is the damage. AMAN is highly associated with antiganglioside antibodies to GM1a, GM1b, and GD1a, which are epitopes on gangliosides. Animal models of AMAN have noted the presence of immunoglobulin G against GM1 and GD1a, along with complement deposition at axolemmal membranes and nodes of Ranvier with limited demyelination and lymphocytic infiltrate.

Gangliosides are cell surface components of nerve tissue. They are glycosphingolipids and consist of a lipid bilayer with an oligosaccharide core. The terminal tetrasaccharide of GM1 gangliosides [Gal(beta 1-3) GalNAc(beta 1-4) NeuAc(alpha 2-3) Gal(beta)] is similar to the lipooligosaccharide of *C. jejuni*, lending credence to the theory of molecular mimicry.

Neuropathic strains of *C. jejuni* more frequently express cst-II, a genetic polymorphism, compared with enteric strains. In particular, patients with cst-II (Thr51) are more likely to be positive for anti-GM1 and anti-GD1a, whereas those with cst-II (Asn51) demonstrate anti-GQ1b antibodies.

The Miller Fisher variant of GBS can be considered a localized subtype, wherein antibodies are produced against GQ1b. GQ1b has been noted to be densely packed in the paranodal regions of the oculomotor nerves (ie, cranial nerves III, IV, and VI). This specific distribution factor would explain the relative frequency of extraocular muscle weakness in this variant.

## **DIAGNOSIS**

### **Symptoms and Signs**

Clinical features common to the various subgroups are discussed initially, and features regarding the individual subtypes are discussed in the latter half of this section.

Clinical events, in the form of an acute infectious illness before the onset of neurologic symptoms, occur in about half of affected children, and these most commonly include an upper respiratory illness.

The disease causes an acute- to subacute-onset quadriparesis or paraparesis. Children usually present with weakness in the lower extremities and can be brought in for refusal to walk, ataxia, or difficulty in climbing stairs. The weakness may then progress to the arms. In a significant minority (15% to 20%) of cases, weakness may remain proximal. Ataxia is caused by a combination of weakness and sensory loss, as opposed to cerebellar pathology. By definition, the nadir of weakness must be reached within 4 weeks, although in most affected children this occurs within 2 weeks.

Cranial nerve involvement (45%) is more frequently noted in children than in adults with GBS. Cranial nerves VII (facial), IX, X (glossopharyngeal and vagus), and VI/III (nerves that subserve extraocular muscles) are involved in that order of frequency. Facial nerve weakness is commonly bilateral. Pupillary involvement is rare, and an alternate diagnoses, such as tick paralysis, should be considered in these cases.

Pain is a common symptom and can be the primary manifestation in 50% of patients. Lower extremities are the most common location for pain, although other regions, including arms, lumbar and cervical regions, and abdomen, can be affected. Pain can be a “red herring” because it may lead to irritability, vomiting, and meningismus, causing diagnostic confusion. Sensory paresthesia can also be fairly prominent and contribute to the pain, although objective findings of sensory loss are rarely present. Distal paresthesia is typically present in both upper and lower extremities simultaneously, which distinguishes it from other polyneuropathies.

Sphincter disturbances, including urinary incontinence, urinary retention, constipation, and fecal incontinence, occur in 10% to 15% of affected children.

Symptoms and signs of dysautonomia may be present in about 25% of cases in the form of hypertension, tachycardia, cardiac arrhythmia, and hypotension. One case has been described of a patient requiring pacemaker placement for atrioventricular block. Mechanical ventilation is required in 15% of cases. Respiratory muscle weakness usually occurs subacutely and correlates with the degree of limb weakness. However, it is possible to have a severe degree of respiratory muscle involvement in the setting of mild limb weakness.

On examination, although the symmetrical nature of the weakness and areflexia is clearly apparent in most cases, patchy involvement may occur on initial presentation. The presence of sensory level is a red flag and should prompt the physician to initiate a search for spinal cord disease.

The natural course of the disease tends to follow 3 stages—progression, plateau, and recovery. The stage of progression is the period when there is immune-mediated damage to the myelin and axons in the nerve fibers. The plateau period represents slowing of the autoimmune-mediated nerve damage. Repair and regeneration of the myelin and axons occurs

in the recovery period. This phase may last for months.

The Miller Fisher variant is characterized by ataxia, areflexia, and ophthalmoplegia. However, this classic constellation of symptoms may not be present. Patients may present with bilateral facial palsy, eye muscle weakness, or central nervous system involvement suggestive of brainstem encephalitis. True motor weakness of the limbs is uncommon. Bickerstaff brainstem encephalitis is a condition that lays along the continuum of the Miller Fisher variant and has been associated with antibodies against GQ1b as well. The clinical features of brainstem encephalitis are mental status changes, ataxia, ophthalmoplegia, and weakness of the bulbar muscles.

Children with AMSAN and AMAN tend to have a more prolonged course with less than complete recovery. Children in this subgroup also have a higher incidence of requiring assisted ventilation.

The AMAN form has the strongest association with preceding *C jejuni* infection. The clinical presentation alone cannot distinguish it from the AIDP and AMSAN varieties.

Polyneuritis cranialis manifests with acute onset of bilateral lower motor neuron VII nerve palsies with frequent involvement of bulbar or extraocular muscles. This condition is distinct from the Miller Fisher variant mentioned previously.

Acute sensory neuropathy commonly presents with acute onset of ataxia with a positive Romberg test. Pandysautonomia causes prominent gastrointestinal and cardiovascular symptoms, reflective of pathology in the sympathetic and parasympathetic nervous system, particularly in the postganglionic efferent fibers.

The use of a clinical grading scale will ensure better communication between physicians (see Table 260-1).

### Differential Diagnosis

The differential diagnosis includes the conditions in Box 260-2. Children with spinal cord pathology, such as myelitis, can have pain and weakness with absent tendon reflexes. The presence of sphincter disturbances can further obscure the picture. Hence, early imaging may be of benefit when trying to differentiate between GBS and myelopathy. When peripheral neuropathy is being considered, usually these conditions

**Table 260-1**

### Guillain-Barré Clinical Grading Scale

0	Normal
1	Minor signs or symptoms
2	Able to walk 5 m without support
3	Able to walk 5 m with a walker or support
4	Bed or wheelchair bound
5	Requires assisted ventilation
6	Dead

Modified with permission from Hughes RAC, Newsom-Davis JM, Perkin GD, Pierce JM. Controlled trial of prednisolone in acute polyneuropathy. *Lancet*. 1978;312(8093):750–753.

can be distinguished by a detailed history and neurologic examination.

### Diagnostic Approach

Initial criteria for the diagnosis of GBS were formulated in 1978 under the auspices of the National Institute of Neurological Diseases and Stroke (NINDS), and subsequent modifications were suggested by Asbury and Cornblath in 1990. In brief, features required for diagnosis include progressive motor weakness of more than 1 limb with areflexia. Features that strongly support diagnosis include progression over 4 weeks, symmetry, cranial nerve involvement, recovery that

begins 2 to 4 weeks after progression stops, and autonomic dysfunction. Cerebrospinal fluid findings and electrophysiologic criteria that lend support include albuminocytologic dissociation and findings suggestive of demyelination, respectively.

More recently, the Dutch Neuromuscular Research Support Centre has proposed the following diagnostic and classification criteria for AIDP:

1. Subacutely developing flaccid paralysis
2. Weakness that tends to be symmetrical
3. Decrease or disappearance of tendon reflexes
4. Other causes for rapidly developing paralysis excluded by history and physical examination and, if necessary, additional testing

### Ancillary Testing

As implied by the previous discussion, a diagnosis of GBS is primarily based on clinical symptoms and neurologic examination. Although diagnostic procedures may lend support, they are not necessary to validate the diagnosis and do not supplant physical signs. In atypical cases, the physician may consider the following ancillary tests to confirm the diagnosis.

#### Laboratory Testing: Spinal Fluid Analysis

As a rule, there should be fewer than 50 cells/mm<sup>3</sup>, but usually there are fewer than 10 cells/mm<sup>3</sup>. A high cell count should raise suspicion for Lyme borreliosis, carcinomatous meningitis, or peripheral neuropathy associated with human immunodeficiency virus (HIV). Half of cases in the first week and 80% in the second week have elevated cerebrospinal fluid protein. In patients with the Miller Fisher variant, albuminocytologic dissociation is present in more than 75% of cases by the second week of illness.

#### Imaging

Enhancement of nerve roots with gadolinium on magnetic resonance imaging of the lumbosacral spine is commonly noted. A 1996 prospective study noted it in 18 of 19 patients with GBS. The disability scale was higher in those with greater enhancement and duration to recovery was longer in this subset. Interestingly, this finding was not related to the timing of imaging with respect to the course of the illness. In the Miller Fisher and polyneuritis cranialis variants, enhancement of the cranial nerves may be present.

### Diagnostic Procedures

**ELECTROPHYSIOLOGY** Care must be taken in deciding when to order nerve conduction studies because they remain normal early in the course of the illness. The earliest change is delayed or absent F waves. Abnormalities in the motor nerve conduction studies are present in 50% by 2 weeks and 85% by 3 weeks. Ten percent of cases may never fulfill the criteria for acquired demyelination. Electrophysiologic criteria, although beyond the scope of this chapter, broadly include the presence of at least 3 of the following:

1. Prolonged distal latency (time from application of the electrical stimulus to the recorded action potential in the muscle).

### BOX 260-2 Differential Diagnosis

#### DISEASES OF THE CENTRAL NERVOUS SYSTEM

Postinfectious cerebellar ataxia  
Structural cerebellar lesions  
Myelopathy

#### DISEASES OF THE PERIPHERAL NERVOUS SYSTEM

Anterior horn cell enteroviral infections, West Nile virus  
Peripheral neuropathy:

1. Noninfectious
  - a. Heavy metal and solvent poisoning: lead, arsenic, mercury, thallium, n-hexane, and organophosphates
  - b. Drug toxicity: isoniazid, nitrofurantoin, vincristine, cisplatin, phenytoin, and vitamin B<sub>6</sub>
  - c. Paraneoplastic polyneuropathy
  - d. Porphyric polyneuropathy
  - e. Critical illness polyneuropathy
  - f. Deficiency states, eg, vitamin B<sub>12</sub> deficiency
2. Infectious: Lyme disease (*Borrelia burgdorferi* infection), HIV, diphtheria. Spinal fluid in these cases usually reveals pleocytosis.
3. Food- and insect-borne polyneuropathy: neurotoxin fish poisoning, tick paralysis

#### NERVE ROOT DISEASE (POLYRADICULOPATHY)

Carcinomatous  
Sarcoidosis  
Lumbosacral plexopathy

#### DISEASES OF THE NEUROMUSCULAR JUNCTION

Myasthenia gravis: When ophthalmoplegia is prominent, this should be considered. Some patients do have proximal muscle weakness, although absence of myotactic reflexes should raise suspicion.  
Botulism, characterized by early loss of pupillary light reflex

#### MUSCLE DISORDERS

Electrolyte imbalances: Hypokalemia, hyperkalemia, hypermagnesemia, and hypophosphatemia can present with muscle weakness. These conditions do not show disease progression over time as is typical of GBS.  
Critical care myopathy  
Mitochondrial myopathy

2. Decreased conduction velocity (measure of the speed of the fastest conduction axons within the nerve).
3. Prolonged F response latency. (The F response is derived from “antidromic” travel of an electrical stimulus up a nerve to the anterior horn cell and orthodromic travel back to the muscle where it is recorded. Delay in recording F waves can be one of the earliest objective signs of GBS.)
4. Conduction block (when propagation of the impulse is completely or partially halted).

Myelin is essential to ensure rapid conduction along nerves. Accordingly, in conditions with predominant demyelination, there is slowing of the conduction velocity and prolongation of distal latencies. The proximal demyelination is reflected in the alterations in the F waves. Although GBS is in most instances predominantly demyelinating, secondary axonal loss may occur, which can be reflected in the needle electromyogram.

Electrophysiology also has a place in predicting the outcome. The compound muscle action potential (CMAP) is the best indicator of poor prognosis because a low CMAP is indicative of a prolonged course.

In essence, weakness is the result of conduction block or axonal damage, whereas paresthesia and pain are the clinical equivalent of sensory nerve damage.

**SEROLOGY** There is a strong correlation in patients with the Miller Fisher syndrome and its related subtypes, such as Bickerstaff encephalitis, and pharyngeal-cervical-brachial weakness with antibodies that react with gangliosides GQ1b, earning them the epithet “anti-GQ1b syndromes.” Anti-GQ1b antibodies are present in the Miller Fisher variant in more than 80% of cases, especially in the first week of the illness. Pure motor types, such as AMAN, demonstrate antibodies to GD1a and GM1a. Immunoglobulin G antibodies against GQ1b and GT1a are associated with rare anatomically limited forms, such as ophthalmoplegia and oropharyngeal palsy. Antibodies against GD1b are associated with sensory ataxia. Serologic evidence of recent *C jejuni* infections is also more common in patients with the Miller Fisher and AMAN variants. Appropriate serologic workup may help with classification and accurate classification of subtypes.

## MANAGEMENT

### Treatment Approach

The most important aspect of management is the early recognition and treatment of impending respiratory failure. Access to a facility that has a critical care unit well equipped to deal with affected children and an intensive care physician who can assist with this treatment is vital.

Pain management should take a close second place because pain can be prominent and the cause of significant morbidity. This is especially crucial in children who may not be able to clearly articulate their symptoms. The physician should be on the lookout for autonomic imbalance and consider intensive care unit admission if there is significant lability of hemodynamic parameters.

General aspects of care in the intensive care setting include hydration, nutrition, and early instatement of physical and occupational therapy. Treatment with immunomodulatory agents is generally employed when the manifestations are more severe, with prominent ataxia or bulbar or respiratory involvement. Treatment within 2 to 4 weeks of symptom onset may decrease recovery time.

### Specific Treatments

Corticosteroids are ineffective in the treatment of GBS.

#### Intravenous Immunoglobulin

No prospective placebo-controlled randomized trial has been conducted to study the role of intravenous immunoglobulin (IVIG) in children with GBS. Nonetheless, the consensus of opinion, on the basis of case series and retrospective analysis, indicates that IVIG can reduce duration of hospitalization and reduce the time to onset of ambulation. The total dose of IVIG is usually 2 g/kg over 3 to 5 days. Once again, there is no trial to indicate efficacy of this dose over other regimes. Common side effects include fever, rigors, chills, headache, rash, and myalgia. Aseptic meningitis, congestive heart failure, and renal failure are serious, but rarely encountered. Anaphylactic reactions in patients with immunoglobulin A deficiency are rare in clinical practice. The report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology recommends use of IVIG in children based on its effectiveness in adults.

#### Plasmapheresis

Plasmapheresis is a more invasive modality of treatment. A universally accepted protocol is not available. Most institutions use an alternate-day protocol ranging from 4 to 8 pheresis treatments. Potential complications can include hypotension, catheter-related infections, bleeding, and hypocalcemia.

A trial comparing plasma exchange to immunoglobulin noted that using a combined regimen with both modalities of treatment was no more effective than using either form of therapy alone. The American Academy of Neurology recommends use of plasmapheresis in adults with severe GBS that interferes with gait or respiratory function. No similar recommendations in children are available as of the last practice parameter in 2011.

## ONGOING CARE

Monitoring weakness by clinical examination and coordinating care with occupational and physical therapists are the main roles of the physician in cases of GBS. If progression of muscle weakness is present over 4 weeks or a relapsing or protracted course over 1 year is noted, alternate diagnoses must be entertained. Chronic inflammatory demyelinating polyneuropathy then becomes a diagnostic consideration.

### Follow-up

After discharge from a hospital setting, patients should continue occupational and physical therapy

services. Return to school may present certain challenges, and the pediatrician may need to advocate for certain allowances, such as use of elevators. Electro-physiology is rarely repeated after the acute period.

### Complications

The most common complications in the acute care setting are weakness of the respiratory muscles and autonomic instability. Other complications may include pneumonia, constipation, gastric paresis, deep vein thrombosis, and pressure sores. Treatment with IVIG carries the risk for certain side effects, as does plasmapheresis, and these have been discussed in the Specific Treatments section.

### Prognosis

More than 90% of children with GBS recover. Those who do not recover completely ambulate independently with minimal residual deficit. The average time-frame for the period of disease progression and the plateau phase is 4 weeks, respectively. A small subset (<5%) of children may progress to a chronic form referred to as chronic inflammatory demyelinating polyneuropathy (CIDP) or have relapses of GBS. Patients with CIDP, by definition, have progressive weakness for more than 2 months since the onset of weakness, with motor and sensory dysfunction in more than 1 limb and hyporeflexia or areflexia on examination. Unlike GBS, CIDP is characterized by relapses and remissions or a slowly progressive course. Electrodiagnostic criteria for the diagnosis of CIDP have been outlined by various academic bodies, including the American Academy of Neurology.

The mortality rate is currently estimated at less than 5%. Deaths are caused by respiratory failure, cardiac arrhythmia, and dysautonomia. As can be seen, it is an acute monophasic illness and in this manner distinguishes itself from other autoimmune peripheral neuropathies. In the Miller Fisher variant, ophthalmoplegia resolves in 1 to 2 months, and ataxia in 3 to 4 months.

### Prevention

Immunization against *Campylobacter* infection in countries where it is endemic may represent a method of disease prevention. However, as of now, no preventative treatments can be offered because vaccines for enterotoxigenic *Escherichia coli* and *Campylobacter* are currently in the preclinical stage. Families of children who have had GBS should discuss potential risks and benefits of receiving the influenza vaccine, although the preponderance of evidence seems to suggest that the benefits of vaccination outweigh the risks. The Centers for Disease Control and Prevention has cautioned physicians regarding administration of the influenza vaccine and the diphtheria, tetanus, and pertussis (DTaP) vaccine to those known to have experienced GBS within 6 weeks after a previous influenza or DTaP vaccination. Reports to the US Vaccine Adverse Events Reporting system shortly after the quadrivalent conjugated meningococcal vaccine raised concerns about a potential association between the vaccine and GBS. However, the Advisory Committee on Immunization Practices

(ACIP) does not consider a history of GBS to be a contraindication to administration of the meningococcal conjugate vaccine, although it remains listed as a precaution on the package insert.

The preponderance of evidence suggests that hepatitis B; measles, mumps and rubella; *Haemophilus influenzae* type B; rabies; and diphtheria and tetanus toxoid vaccines need not be withheld after an attack of GBS.

### WHEN TO REFER

- A neurologic consultation may be appropriate when a child with suspected GBS is admitted. This may be particularly crucial when the diagnosis is in doubt because of unusual clinical features or the recovery phase is atypical. A neurologist versed in electromyography can help with prognostication.
- Occupational and physical therapy referrals, when done early in the disease process, can be helpful both in the inpatient and outpatient settings to ensure prevention of joint contractures and optimize potential for functional recovery.
- A hospitalist well acquainted with the disease manifestations may prove invaluable in deciding on transfer to a facility that has a pediatric intensive care unit.

### WHEN TO ADMIT

- Any child suspected of having GBS should be admitted to the hospital for observation and close monitoring of respiratory status until it is clear that there is no further disease progression.

## Chapter 261

# HEMANGIOMAS

Jugal S. Arneja, MD, MBA; Alex Benson, MBBS, MSc;  
Mirko S. Gilardino, MD, MSc

## FOUNDATION

### Nomenclature and Classification

Confusing and nonspecific names for hemangiomas, including strawberry nevus and cavernous hemangioma, have been used throughout history. In their seminal work in 1982, Mulliken and Glowacki separated vascular anomalies into hemangiomas and vascular malformations based on their biologic properties. Infantile hemangioma, a type of vascular tumor, grows shortly after birth and slowly involutes through childhood, whereas a vascular malformation is present at birth, continues to grow, and does not resolve spontaneously. In contrast to vascular malformations, hemangiomas have different phenotypic presentations, the most common being the infantile hemangioma. Box 261-1 illustrates the most recent classification for vascular anomalies adopted by the International Society for the Study of Vascular Anomalies.

### Epidemiology, Etiology, and Risk Factors

Infantile hemangioma is the most common tumor of infancy. Classically, these lesions present shortly after birth, with or without an initial precursor lesion or “herald patch,” and subsequently undergo several phases of unpredictable duration characterized by a proliferative phase, a plateau phase and finally, some degree of an involution phase; current thought is that the plateau phase is a balance between proliferation and involution.

In white term infants of normal birth weight, infantile hemangioma incidence is approximately 5% to 10%; for infants with a lower birth weight, the incidence is much greater. About 1 in 5 children will have multiple lesions, and the incidence is 3 times greater for girls. The exact pattern of genetic inheritance is unclear; it is thought that infantile hemangioma inheritance is sporadic. Previous case series and retrospective studies have suggested that female gender, prematurity, fair skin, and history of chorionic villous sampling may all be risk factors for the development of infantile hemangioma.

The exact cause for hemangioma has not been established; however, demographic, prenatal, and perinatal factors in patients with these lesions may provide clues to pathogenesis. There is general consensus that infantile hemangioma is of endothelial cell origin, but the source of the endothelial cells is debatable. There has been much conjecture as to whether these endothelial cells are of mutational or placental origin, if they fit into a developmental field defect, or if they are simply a derangement of angiogenesis. The expression of cellular markers of angiogenesis supports the theory that infantile hemangioma represents vasculature of placental origin or immature vascular growth expressing a placental phenotype.

### Natural History

Classically, the common postnatally acquired infantile hemangioma begins developing after birth and in some cases a precursor herald patch is seen. The herald patch appears in a variety of forms, including a bruise-like patch, a limited area of pallor with fine telangiectasia, or a macular erythematous lesion, or it may even be erroneously attributed to trauma. These lesions develop into a rapidly growing vascular tumor within the first 1 to 2 months of life, characterizing the proliferative phase, and while most growth is completed by 3 to 6 months, growth can continue to 9 months of life. In the plateau/early involution phase, several clinical changes may be seen, including color fading, softening, and reduction in volume. Involution continues with a decreased volume of tumor; however, this process may take several years and is often incomplete. In fact, many infantile hemangiomas leave behind residual cutaneous telangiectasia, scarring, fibrofatty residuum, or excess skin.

When a lesion is present at birth, a vascular malformation should be considered. These lesions are congenital structural anomalies that represent abnormal vasculature or lymphatics. Deeper malformations may only present with clinical symptoms or signs during the adolescent growth period.

## DIAGNOSIS

### Signs and Symptoms

A detailed history and clinical examination are still the most valuable diagnostic tools for infantile hemangioma. The most critical information is the presence of a growth shortly after birth followed by expansion of the lesion and then a period of plateau, culminating with involution. The clinical appearance of an infantile hemangioma depends on which level of the skin is affected; common presentations include superficial cutaneous, deep, or segmental plaque-like. Superficial cutaneous hemangiomas, previously named “strawberries,” are the raised, red tumors that are commonly seen. Their surface comprises a thin epidermal layer and is fragile and prone to injury. During the rapidly proliferative phase, ulceration is a possibility because of the thin epidermal layer which can easily become traumatized; an ulcerated hemangioma should prompt an early referral to a specialist. Deep lesions are located in the deeper dermis and subcuticular space; because of their depth, the perceived color is generally darker, and the lesion could be confused for a vascular malformation (usually venous malformation) or another solid lesion. Visible telangiectasia, dilated small vessels, or vascular papules can be associated with these deeper lesions, especially with draining veins at the periphery. Occasionally, hemangioma presents as a flat, plaque-like segmental lesion that grows radially, but does not develop into the more classical “fleshy” appearance. In certain anatomic locations, these lesions should warrant further evaluation. Hemangiomas can also be further classified as being of high risk (functional or aesthetic complications) or low risk (no functional or aesthetic concern). High-risk lesions are discussed in detail later in this chapter.

### Differential Diagnosis

Although infantile hemangioma is the most common presentation of a vascular birthmark, the differential diagnosis includes other types of vascular tumors (congenital hemangioma, pyogenic granuloma, tufted angioma, and kaposiform hemangioepithelioma [KHE]) as well as vascular malformations (capillary malformation, venous malformation, lymphatic malformation, arteriovenous malformation, and mixed malformations); if presenting with a subcutaneous mass, lesions to consider, include lipoma, neurofibroma, and rhabdomyosarcoma, among others.

Different subtypes of hemangioma, rapidly involuting congenital hemangioma (RICH) and non-involuting congenital hemangioma (NICH), present fully grown at birth and may be detected by ultrasound prenatally. These lesions are usually found on the head and neck or lower limbs and have similar imaging findings, but different temporal courses. RICH commonly presents as a single raised tumor that has a dark color with central telangiectasia, has a radial distribution of ectatic veins, and is surrounded by a pale halo region. These lesions do not grow, and they involute by 12 to 18 months. NICH is a solitary tumor, resembles a RICH clinically, grows with the patient or expands slightly over time, but does not regress.

Another vascular tumor that might resemble an infantile hemangioma is a pyogenic granuloma. Although presenting at any age, historically these were often known as “pregnancy tumors” and may be related to trauma. More commonly found in children, these grow rapidly to vascular and friable papules or tumors. They are most commonly found on the head and neck, but other sites have been described. These lesions often ulcerate and bleed, and are prone to recurrence with subtotal treatment.

KHE is a rare entity that may be found either in skin or as a retroperitoneal tumor. This lesion presents as a congenital tumor or develops shortly after birth. Histologic examination demonstrates dense and infiltrating spindle cell nodules with infrequent mitoses. Tufted angioma is another uncommon vascular tumor that usually presents in infancy or childhood, but has been found congenitally. This is a diffuse group of lesions including solitary tumors, large plaques or “port wine stain-like” lesions with a cobblestone presentation. The association with Kasabach-Merritt phenomenon (systemic coagulopathy resulting from thrombocytopenia) is established for KHE and tufted angiomas.

Vascular malformations, in contrast to infantile hemangioma, are present at birth, grow in proportion to the child, and may proliferate during periods of hormonal fluctuation (ie, puberty, pregnancy). Interestingly and of diagnostic concern, in the neonatal period the differential diagnosis of a cutaneous red patch might represent the early stages of a proliferating hemangioma, a congenital hemangioma, a capillary malformation, or a stage I arteriovenous malformation. A detailed discussion of vascular malformations can be found in Chapter 95, Neonatal Skin.

### High-Risk Lesions: Complications and Associations

#### Segmental Hemangioma

Specifically pertaining to infantile hemangioma, these lesions can be further subclassified depending on their pattern, type, and association with other lesions (see Box 261-2).

Segmental plaque-like hemangiomas in certain anatomic locations often warrant additional evaluation because of associated conditions that can be present. Large segmental hemangiomas in the facial region warrant consideration for PHACES syndrome, characterized by posterior fossa malformations; facial hemangiomas; arterial, cardiac, and eye abnormalities; and sternal clefting. Lumbar or pelvic segmental hemangioma may be associated with LUMBAR syndrome, manifested by arterial anomalies, spinal cord tethering, perineal-lumbosacral hemangioma, and genitourinary differences.

#### Visceral Hemangioma

About 15% of children will have more than 1 cutaneous hemangioma. The presence of more than 5 lesions can be associated with visceral involvement, and investigation by ultrasound or magnetic resonance imaging (MRI) for intra-abdominal hemangioma is recommended. Ultrasonography is the indicated screening test; MRI should only be done if ultrasound

**BOX 261-2 Classification of Infantile Hemangioma****PATTERN**

- Focal
- Multifocal
- Segmental
- Indeterminate

**DIFFERENT TYPES**

- Superficial
- Deep
- Mixed (superficial + deep)
- Reticular/abortive/minimal growth
- Others

**ASSOCIATION WITH OTHER LESIONS**

- PHACES syndrome
  - Posterior fossa malformations
  - Hemangioma
  - Arterial anomalies
  - Cardiovascular anomalies
  - Eye anomalies
  - Sternal clefting or supraumbilical raphe
- LUMBAR (SACRAL, PELVIS) syndrome
  - Lower body hemangioma
  - Urogenital anomalies
  - Ulceration
  - Myelopathy

shows lesions that are concerning for another diagnosis.

Intra-abdominal hemangioma most often manifests as a liver hemangioma, which is the most common pediatric hepatic lesion; the presenting feature clinically could be high-output cardiac failure. A single, large lesion detected by antenatal imaging or on physical examination or imaging at birth is usually a rapidly involuting congenital hemangioma. This type of lesion may be asymptomatic and require no therapy. It also may be associated with high-flow shunts causing high-output cardiac failure. These symptoms/signs may improve with rapid spontaneous involution, or may require embolization of high-flow shunts.

Multifocal lesions may be asymptomatic or may demonstrate high-flow causing high-output cardiac status. This should be treated with propranolol and followed closely. Many multifocal or closely packed, diffuse hemangiomas may cause consumptive hypothyroidism, which should always be investigated and treated aggressively if found.

**Airway Hemangioma**

Upper airway hemangioma (sometimes called subglottic hemangioma) carries a significant risk of airway compromise during the proliferative phase and usually presents clinically with stridor. About half of these infants will have a cutaneous lesion, but those with perioral lesions seem to be at the highest risk (60% of those with a “beard distribution” lesion will develop symptomatic upper airway difficulty). Respiratory failure can occur precipitously, and the combination of cutaneous infantile hemangioma and respiratory distress should warrant prompt referral to an otolaryngologist experienced in pediatric airway management.

**Periocular Hemangioma**

Up to 50% of periocular hemangiomas are amblyogenic, most commonly from refractive error (astigmatism, anisometropia) resulting from pressure imparted by an adnexal tumor on the cornea. Furthermore, amblyopia can be caused by deprivation from visual axis obstruction, optic nerve atrophy secondary to nerve compression or stretch, strabismus caused by tumor infiltration of extraocular muscles, or keratopathy caused by proptosis and corneal exposure. Infrequently, an infant presents with a lesion covering the visual field; patching of the normal eye may be indicated. These lesions must be urgently evaluated by an ophthalmologist to prevent irreversible amblyopia, and aggressive intervention could be warranted.

**Ulceration and Infection**

Ulceration is a common finding in patients with infantile hemangioma. Risk factors for hemangioma ulceration include large size; segmental distribution; regions prone to friction, trauma or maceration (perineum, lip); lesions in the proliferative phase; female gender; and premature birth. Ulceration can be caused by trauma or maceration. These lesions are notoriously challenging to manage, because they may take several weeks to heal regardless of which modality of treatment is employed. Furthermore, an ulcerated infantile hemangioma is very painful, and careful dressing care is important so as to avoid further trauma to an already complex wound.

A small subset of hemangiomas may become infected, and infection is associated with an ulcerated lesion because the open area can become colonized with bacteria, especially in the perineal-lumbosacral area. Once an infantile hemangioma becomes ulcerated, care should be taken to dress the ulcerated wound with a topical non-stick antimicrobial agent, which may help enhance wound healing rates, because colonized wounds take longer to heal.

Many of the common complications of infantile hemangioma include wound care issues. For perineal-lumbosacral lesions, frequent soiling and maceration can lead to ulceration, bleeding, and pain. Parent education regarding meticulous wound care in the form of topical antimicrobials and non-stick wound dressings is paramount.

**Other**

Hypothyroidism has been described in infants with massive hemangioma because of high levels of type 3

iodothyronine deiodinase within the lesion. In patients with large or multiple lesions, investigation of thyroid function may be required. Finally, lesions obstructing the auditory canal or perineal-lumbosacral region warrant specialist evaluation by an otolaryngologist or urologist/general surgeon, respectively.

### Imaging

The diagnosis of hemangioma is primarily clinical in nature, based on history. Plain radiography rarely aids in diagnosis; however Doppler ultrasonography and MRI may help guide diagnostics or management planning. In rare cases, a biopsy may be performed to rule out any other pathology. Doppler ultrasonography may demonstrate a well-circumscribed mass within which are anechoic channels and numerous fast-flow vessels. The flow should be correlated with the clinical stage of the lesion, because the arterial flow will be reduced during the involutional phase. Throughout the proliferative phase, there are numerous vessels with a high Doppler shift ( $>2$  kHz), low resistance, and nonspecific echogenicity.

MRI is useful for lesions causing a diagnostic dilemma as well as for presurgical planning to determine anatomic relationships between the tumor and the surrounding tissues. Well circumscribed, uniformly enhancing and densely lobulated structures with multiple flow voids as well as dilated arterial feeding and venous draining vessels, either at the periphery or within the center of the lesion, are characteristic findings that can be seen on MRI.

### Histopathology

Histopathologic findings of infantile hemangioma change according to the phase of its natural history. Early proliferative phase findings include plump endothelia with surrounding pericytes in unencapsulated and well-defined clumps and lobular arrangement of the lesion with large feeding and draining vessels. Many mitoses can be seen, but they are of a normal morphology. During this period of growth, the vascular endothelia undergo several changes with sinusoidal channels that are closely packed. Throughout the involutional phase, the number of mitoses and vessels decreases and fatty infiltration of the mass occurs. Increased mast cell proliferation is evident at the onset of involution and resolves during the involutional phase. A multilaminated basement membrane is seen with electron microscopy, but this is seldom practical or required for diagnosis. The immunohistochemical marker, GLUT-1, is found in all phases of the lesion's natural history and is helpful in differentiating infantile hemangioma from other vascular anomalies. Interestingly, congenital hemangiomas (RICH/NICH) are GLUT-1 negative.

## MANAGEMENT

### Treatment Approach

The benefits of any treatment must be weighed and balanced appropriately against the presenting problem. For an infantile hemangioma, the decision to employ observational management, medical management, or operative management is subject to debate.

In the 1940s through the 1960s, patients were given radiation therapy that effectively treated the lesion but also produced secondary undesirable sequelae. As a result, through the 1970s and 1980s, a hesitancy from the perspective of primary care physicians and dermatologists toward aggressive treatment was espoused. Since the 1990s, though, more aggressive and earlier treatment approaches have been the trend because infantile hemangiomas often do not involute completely, leaving behind excess skin, fibrofatty tissue, scarring, and telangiectasia.

Although there are numerous possible treatment options for hemangioma, this produces a treatment dilemma, because no definitive advice exists to guide the physician. In general, small, uncomplicated, low-risk lesions in unimportant cosmetic or functional areas may be managed without intervention, because spontaneous resolution is likely to yield an acceptable aesthetic and functional result. High-risk lesions producing functional or aesthetic distortion should prompt timely referral to a vascular anomalies team for additional evaluation and treatment considerations.

### Specific Treatments

#### Observational Management

For patients with low-risk lesions, regular visits to the primary care physician during the proliferative period are required, for both patient monitoring and reassurance. Photographic aids describing hemangioma natural history should be shared to limit parental anxiety. A multidisciplinary approach may also be helpful involving dermatologists, plastic surgeons, general surgeons, ophthalmologists, otolaryngologists, among others.

#### Medical Management

**CORTICOSTEROIDS.** Over the past 40 years, the mainstay of medical treatment for infantile hemangioma has been corticosteroids administered either systemically or intralesionally. Treatment is most effective in the rapidly proliferative phase, and on occasion rebound growth is found on cessation of therapy. The documented side effects of systemic corticosteroids (including irritability, cushingoid facies, hypertension, and gastroesophageal reflux) should be explained prior to initiation, and screened for while the patient is on the medication; these potential complications are temporary and resolve with discontinuation of treatment. Delivery of corticosteroid by injection can also be effective, although the sequelae of cutaneous atrophy, telangiectasia, and pigmentary changes can occur. Despite the complication profile, dramatic results have been found with corticosteroid administration, purportedly as a result of angiogenesis inhibition.

**BETA-BLOCKERS.** A recently discovered treatment modality for infantile hemangioma has been found through the use of the nonselective beta-blocker, propranolol. This drug has been the source of much interest, and numerous case series have found promising results in not only the proliferative phase, but also the plateau and involutional phases. The exact mechanism of action of beta-blockers for the treatment of hemangioma remains uncertain, although

**Figure 261-1** Clinical photographs of a 3-month-old infant with an extensive right facial hemangioma. (Top Row) Note the visual axis obstruction and impending obstruction of right nostril. (Center Row) There was a significant decrease in subcutaneous tumor bulk 1 month after treatment. (Bottom Row) Clinical photographs of the patient after treatment with oral propranolol for 6 months. Note the significant improvement of proptosis, facial contour, and right nostril position. (From Arneja JS, Pappas PN, Shwayder TA, et al. Management of complicated facial hemangiomas with beta-blocker [Propranolol] therapy. *Plast Reconstr Surg.* 2010;126:889–895, with permission.)

some hypotheses have suggested a vasoconstrictive, antiangiogenic, or cellular apoptosis effect. Propranolol has been administered orally at 2 (range 1–3) mg/kg/day in twice-daily or 3-times daily dosing. Complications to be screened for include bronchospasm, hypoglycemia, hypotension, and bradycardia; other potential complications can include limb cyanosis, hyperkalemia, and seizures. Although the long-term effects and efficacy of this therapy have not been established, early evidence suggests the complication profile is found less often than with corticosteroid, and outcomes to date are very encouraging. Figure 261-1 illustrates successful management of a large facial amblyogenic hemangioma with propranolol in the setting of failed and complicated corticosteroid treatment. Recently, the topical delivery

of beta-blocker has also met with clinical success and without the potential complication profile of medication taken orally.

**OTHERS.** Interferon- $\alpha$ , an angiogenesis inhibitor, has been used for hemangioma management, and both the isoforms 2 $\alpha$  and 2 $\beta$  have been used with equal success. Significant neurotoxicity in about 20% of cases (spastic diplegia) has limited the utility of this therapy. Vinca alkaloids have also been used with success, but are used much less often today.

#### Laser Therapy

Several different types of lasers have been developed to treat intact and ulcerated infantile hemangioma. The pulsed dye laser has been shown to be effective in

**Figure 261-2** Photographs of a 6-month-old girl with left lateral upper eyelid hemangioma causing blepharoptosis and astigmatism (3.0 diopters) preoperatively (left) and 15 months postoperatively (right), with astigmatism improvement (0.5 diopters). (From Arneja JS, Mulliken JB. Resection of amblyogenic periocular hemangiomas: indications and outcomes. *Plast Reconstr Surg.* 2010;125:274-281, with permission.)

the management of capillary malformations (port-wine stains), and has been widely used for the treatment of hemangiomas. Because its depth of penetration is only approximately 1 to 2 mm, the pulsed dye laser is used primarily to treat the cutaneous manifestations of the lesion. It may be most useful for treating the residual telangiectasia after involution, or for treating ulcerated infantile hemangioma. Multiple treatments might be necessary for optimization of aesthetics. Continuous-wave lasers such as the argon, neodymium:yttrium-aluminum-garnet (Nd:YAG) and potassium titanyl phosphate (KTP) have also been used, albeit less commonly than the pulsed dye laser.

### **Surgical Management**

The indications for patients with hemangioma to undergo surgery are varied, but can be divided according to phase or degree of complication. Complicated infantile hemangioma failing medical therapy should be considered for a surgical opinion, because left untreated it can produce permanent or undesirable sequelae. Furthermore, a facial hemangioma producing aesthetic distortion can also be considered for resection, because these tumors impart a significant degree of caregiver and patient anxiety and distress. Consideration should also be given to the development of the patient's facial image and self-concept, because this begins between 3 and 6 years of age, and peer ridicule can be problematic through the primary school years. For lesions producing aesthetic distortion, careful dialogue between patient, caregivers, and physician/

surgeon is necessary to determine appropriateness and timing of surgical intervention.

Surgical techniques go beyond the scope of this chapter; however, the figures herein illustrate what outcomes are possible with surgical intervention of an amblyogenic periocular hemangioma (Figure 261-2), a nasal tip hemangioma producing aesthetic distortion (Figure 261-3), and a symptomatic upper lip hemangioma (Figure 261-4).

## **ONGOING CARE**

### **Follow-Up**

For low-risk lesions, regular follow-up should occur during the proliferative phase and should be of a supervisory nature through the involutional phase. Primary care physicians should consider referral for optimization of final aesthetic outcome. Of note, early in the infantile hemangioma natural history, it is important to follow patients at regular weekly/biweekly intervals, because during the proliferative phase of rapid growth a relatively innocuously appearing lesion might become a high-risk lesion over the course of only a few weeks. High-risk lesions should be followed and managed according to specialist recommendations. Patients treated with medical therapy should be followed carefully to monitor progress and manage complications.

### **Prognosis**

Although infantile hemangioma is a benign tumor, the best way to characterize the lesion is by its

**Figure 261-3** Combined medical and surgical management resulted in an optimum aesthetic result in this patient. A bulbous, pigmented hemangioma is evident at 6 months of age (top). Following completion of treatment with intralesional steroids and pulsed dye lasertherapy, at age 3 years (center), the lesion has decreased in size, and cutaneous manifestations have resolved. Surgical correction was subsequently performed at 5 years of age, and served to “sculpt” the final appearance of the nose. A satisfactory result 1 year postoperatively (bottom). (From Arneja JS, et al. The “Cyrano Nose”: refinements in surgical technique and treatment approach to hemangiomas of the nasal tip. *Plast Reconstr Surg.* 2010;126:1291–1299, with permission.)

unpredictability. It is impossible to predict how long a tumor’s period of growth will be, how large it will become, what complications it will produce, how long the distinct phases will be, and to what degree it will involute. The potential exists for the development of

functional complications, associated conditions, and aesthetic distortion. It was classically described that 50% of hemangiomas involute by age 5, 70% by age 7, and 90% by age 9; however, these metrics are no longer considered reliable, because recent evidence

**Figure 261-4** A 12-month-old girl with a proliferative hemangioma of the upper lip (clockwise from bottom left) preoperatively, intraoperatively, and 1 year postoperatively. The hemangioma interfered with feeding, and this resolved after resection. (From Hynes S, et al. *Complicated infantile hemangioma of the lip: outcomes of early versus late resection*. *Plast Reconstr Surg*. 2013;131:373e–379e, with permission.)

illustrates that “approximately 20% to 40% of patients will have residual and disfiguring skin changes,” suggesting that a great number of lesions do not involute completely. Accordingly, to prevent long-term complications (functional and aesthetic), high-risk lesions should be treated aggressively, because complete involution is often unlikely and early treatment may prevent adverse sequelae.

#### WHEN TO REFER

- Ulceration
- Periocular lesion
- Airway symptoms (stridor, respiratory distress) or beard distribution
- Perineal-lumbosacral lesion
- Segmental lesion (facial, perineal-lower limb)
- Aesthetic distortion (cosmesis/deforming)
- Multiple lesions
- Uncertain diagnosis

#### WHEN TO ADMIT

- High-output cardiac failure
- Airway compromise

#### TOOLS FOR PRACTICE

##### Engaging Patient and Family

#### Chapter 262

### HEMOGLOBINOPATHIES AND SICKLE CELL DISEASE

Meera Chitlur, MD; Sharada A. Sarnaik, MD

The inherited hemoglobin disorders comprise the most common single-gene defects in humans. Worldwide, the frequency of the carrier state is estimated to be 270 million, with approximately 400,000 annual births per year of infants with serious hemoglobinopathies. The prevalence of hemoglobinopathies is on

the rise worldwide. This prevalence is of special importance in developing countries, where it increases the burden of the health care delivery system. In the United States and other developed countries, hemoglobinopathies remain a concern, particularly among certain ethnic populations.

### NORMAL HEMOGLOBIN STRUCTURE

Hemoglobin is a tetrameric protein with 4 peptide chains, 2  $\alpha$  or  $\alpha$ -like chains and 2 non- $\alpha$  (or  $\beta$ -like) chains. The molecule is held together by interactions between peptide chains. The amino acids in the globin polypeptide chain are assembled in a long, convoluted knot; lying within the knot is the heme moiety, which carries within it a molecule of oxygen. Its iron is in the  $\text{Fe}^{2+}$  form, and it does not change its valence with release of oxygen. Abnormalities that result in a change to the ferric form (methemoglobin, or hemoglobin [Hb] M) result in a hemoglobin molecule that is unable to carry oxygen. The  $\alpha_1\text{-}\beta_2$  interface is an important region for the unique oxygen-carrying function of hemoglobin, and abnormalities in this area will alter its oxygen affinity. The areas of the molecule where the globin chains are in contact with each other or with the heme molecules are functionally important and are evolutionarily highly conserved.

### GENETICS OF HEMOGLOBIN SYNTHESIS

The normal hemoglobins are adult hemoglobin (Hb A; 96% of the total content), fetal hemoglobin (Hb F; 1%), and hemoglobin A<sub>2</sub> (3%). Hemoglobin synthesis is directed by controlling genes that are switched on and off at certain stages of human life, resulting in different globin-chain synthesis at different times.

The first globin chains to be produced are the  $\epsilon$  chains, which have similar structural sequences to  $\beta$  chains, followed by the production of  $\alpha$ ,  $\zeta$ , and  $\gamma$  chains. This production results in the formation of the early fetal hemoglobins such as Hb Gower 2 ( $\alpha_2\epsilon_2$ ), Hb Portland ( $\zeta_2\gamma_2$ ), and Hb F ( $\alpha_2\gamma_2$ ). At birth, 55% to 65% of total hemoglobin synthesized is Hb F. A switch from  $\gamma$ -chain to  $\beta$ -chain production starts at approximately the ninth gestational week, when Hb A ( $\alpha_2\beta_2$ ), the predominant hemoglobin in adult red blood cells (RBCs), becomes detectable. Fetal hemoglobin synthesis declines but persists until 9 months of postnatal age, at which time the switch is complete. (This process also explains why  $\beta$ -chain abnormalities do not manifest clinically at birth.) A small amount of fetal hemoglobin ( $\leq 1\%$ ) persists in adults in a small clone of cells called F cells. The switching from Hb F to Hb A is delayed in infants of mothers with diabetes, in infants with metabolic diseases characterized by an inability to metabolize propionic acid, and in infants with chronic bronchopulmonary dysplasia.

The third (minor) normal hemoglobin seen in adults is Hb A<sub>2</sub> ( $\alpha_2\delta_2$ ). Normal A<sub>2</sub> levels are 1% to 3%. The importance of Hb A<sub>2</sub> is that it is increased in the  $\beta$ -thalassemias, and this helps in the diagnosis of  $\beta$ -thalassemia trait.

The genes controlling  $\alpha$ -like globin chains are located on chromosome 16, whereas genes for  $\beta$ -like chains are located on chromosome 11. Globin gene

expression is under intense research scrutiny because of the therapeutic possibilities of preferentially stimulating Hb F synthesis (by gene manipulation) to ameliorate  $\beta$ -chain disorders.

### SCREENING AND GENETIC DIAGNOSIS

The primary reason to screen patients for hemoglobinopathies is to identify their risk for producing offspring with a clinically important disease such as  $\beta$ -thalassemia major, sickle cell disease, or  $\alpha$ -thalassemia major (hydrops fetalis).

Screening can involve a simple test, such as a complete blood count, while paying attention to the RBC indices. Thalassemias are usually associated with a low mean cell volume (microcytosis), normal or near-normal mean cell hemoglobin concentration, increased or normal RBC count, and a normal or decreased hemoglobin concentration. Iron deficiency can present with similar indices, with the exception of the RBC count that is low (not increased or normal). It is prudent, however, to exclude iron deficiency before evaluating thalassemia trait. If iron studies are normal, then a hemoglobin evaluation or electrophoresis should be obtained to evaluate for increased Hb A<sub>2</sub> and Hb F, which suggests a diagnosis of  $\beta$ -thalassemia trait. Hemoglobin electrophoresis will also demonstrate structurally abnormal hemoglobins, such as Hb C, Hb S, or Hb E.

A prenatal diagnosis of a clinically important hemoglobinopathy can be made by DNA analysis by sampling fetal blood or the chorionic villus.

### CLASSIFICATION OF ABNORMAL HEMOGLOBIN SYNTHESIS

Abnormal hemoglobin synthesis is the result of the production of structurally normal, but decreased, amounts of globin chains (the thalassemias), production of structurally abnormal globin chains (Hb S, C, E), or failure to switch globin chain synthesis (hereditary persistence of fetal hemoglobin).

Inheritance of all these disorders is autosomal codominant. *Codominant* is the most accurate term because heterozygosity carries discernible, but minor, clinical findings.

### THALASSEMIAS

In 1925, a severe form of anemia and splenomegaly with characteristic bone changes was described in children of Italian origin. A milder form of the same condition was later described by several Italian investigators. Because all of the cases were reported in children of Mediterranean origin, the disease was called *thalassemia*, from the Greek word *thalassa*, meaning *sea*. Later, research showed that cases of the homozygous or compound heterozygous states were not confined to the Mediterranean area, but occurred throughout the tropical countries. The 2 important forms of this disorder,  $\alpha$ - and  $\beta$ -thalassemia, are now recognized as the most common monogenic diseases in humans.

The thalassemias, which are all caused by mutations in the globin gene cluster, result in a genetic decrease in globin chain synthesis. Theoretically, as many types of thalassemias exist as types of globin chains. Practically, the most clinically relevant thalassemias are  $\alpha$ - and  $\beta$ -thalassemia. The defects are

numerous—more than 200 different mutations have been described—and include deletional and nondeletional mutations. Mutations usually have a geographic and ethnic distribution.

### **α-Thalassemias**

#### **Definitions and Clinical Manifestations**

α-Thalassemias are characterized by decreased α-globin synthesis. The most common defect is deletional, although nondeletional defects have also been described. The α gene is duplicated, and 2 α-globin genes per haploid genome are present; thus, the abnormality can result from 1 to 4 gene deletions. α-Globin gene expression occurs throughout intrauterine life. Hence, serious gene mutations can have deleterious effects on fetal development, and death in utero may result. In contrast, deleterious gene mutations in the β-globin chain are manifest only several months after birth, when the switch from γ- to β-globin production is complete.

Recently accepted classification of the α-thalassemias is similar to the β-thalassemias: α<sup>0</sup> in which no normal α-globin is produced by the gene and α<sup>+</sup> in which globin product is reduced. When a single gene deletion and 3 intact genes exist, no abnormality is discernible; this state is known as the silent carrier state. The 2-gene deletion results in a minor clinical condition, with mild hypochromic, microcytic anemia, similar to iron deficiency. α-Thalassemia major results from deletion of 3 or more α-globin genes. Deletion of 3 genes, or Hb H (β-tetramer) disease, results in moderate anemia that is hypochromic and microcytic; hepatosplenomegaly caused by extramedullary hematopoiesis results. Deletion of all 4 genes is incompatible with life and results in hydrops fetalis or intrauterine death (Table 262-1). Recent development of successful intrauterine diagnosis of 4 gene deletions has allowed intrauterine blood transfusions of the fetus, and viable births have been possible.

#### **Differential Diagnosis**

Complete blood count shows hypochromia (mean cell Hb <27 pg); microcytosis (low mean corpuscular volume), and mild anemia. Confirmation of decreased

α chains is done by globin-chain analysis measured in reticulocytes, although this is expensive and difficult. Restriction fragment length polymorphism is reserved for prenatal diagnosis. Decreased α chains result in an excess of non-α chains, which are insoluble and form tetramers. These abnormal hemoglobin tetramers are shown by the presence of RBC inclusions on cresyl blue stain and by hemoglobin electrophoresis. They are rapid moving (faster than Hb A) and require special attention if older techniques of paper or gel electrophoresis are used. High-performance liquid chromatography has become the test of choice for the diagnosis of thalassemias and hemoglobinopathies because it reliably separates hemoglobin types. Hemoglobin Bart (γ-globin tetramers) is found in the first few weeks of life, and Hb H (β-globin tetramers) can be found in older patients.

Because the genes for α- and β-thalassemia are on separate chromosomes, they can be coinherited. Coinheritance of α-thalassemia can have beneficial effects on clinical severity in the phenotype of β-thalassemia, as well as the structural hemoglobinopathies, such as sickle cell disease.

**HEMOGLOBIN H DISEASE.** Patients with Hb H disease have only 1 functional α-globin gene, often the result of deletion of the 3 other α-globin genes. Twenty percent of patients have deletion of 2 genes along with a nondeletional mutation of the third gene. The most common nondeletional mutation of the α-globin gene results in a slow-moving hemoglobin called hemoglobin constant spring (Hb CS). Clinically, Hb H disease is characterized by hemolytic anemia of variable severity and splenomegaly. A serious drop in hemoglobin can occur with infections or with ingestion of substances that induce oxidant stress. Additionally, Hb H hydrops fetalis syndrome is a devastating complication associated with the nondeletional forms of Hb H disease. It is associated with similar fetal and maternal complications as Hb Bart hydrops fetalis, including death in utero.

**HEMOGLOBIN BART DISEASE.** If both parents carry the α<sup>0</sup>-thalassemia mutation in cis (−/+), then a 25% chance with each pregnancy exists that the offspring will inherit both sets of mutations and therefore

**Table 262-1** Classification of the α-Thalassemias

PHENOTYPE	NUMBER OF α GENES	α/β SYNTHETIC RATIO	HAPLOTYPE	GENOTYPE	CLINICAL FEATURES
Normal	4	1.0	α, α	αα/αα	None
Silent carrier	3	0.8	α <sup>+</sup> , α	−α/αα	No anemia, normal rbc count
2-Gene deletion (α-thalassemia 1)	2	0.6	α <sup>0</sup> , α or α <sup>+</sup> , α <sup>+</sup>	−−/αα or −α/−α	Mild anemia, hypochromia, and microcytosis
Hb H disease	1	0.3	α <sup>0</sup> , α <sup>+</sup>	−−/−α	Moderate anemia, fragmented cells with hypochromia and microcytosis
Hydrops fetalis	0	0	α <sup>0</sup> , α <sup>0</sup>	−−/−−	Death in utero caused by severe anemia

α, normal alpha globin; α<sup>0</sup>, No normal α-globin; α<sup>+</sup>, globin is reduced; Hb, hemoglobin; RBC, red blood cell.

lack all 4 genes for production of  $\alpha$ -globin chains. Many of these fetuses survive into the second or third trimester of pregnancy because of persistence of the embryonic  $\zeta$ -globin chains. The fetus, however, will experience serious consequences, such as anemia and hypoxia with resultant organ and cognitive dysfunction. They invariably die in utero or shortly after birth, unless treated with intrauterine blood transfusions. The  $\alpha^0$ -thalassemia mutation is also associated with life-threatening complications to the mother such as placentomegaly, hypertension and preeclampsia, disseminated intravascular coagulation, and hemorrhage. This syndrome accounts for 90% of all non-immune hydrops fetalis cases in Southeast Asia.

$\alpha$ -Thalassemia is also seen in nontropical populations in association with intellectual disability and is known as  $\alpha$ -thalassemia mental retardation (ATR). The association demonstrates 2 unusual features—first, it occurs in racial groups in which  $\alpha$ -thalassemia is otherwise rare, and second, the pattern of inheritance is different from that seen in  $\alpha$ -thalassemia. This pattern occurs in association with a deletion on chromosome 16 (ATR-16) and in association with the ATR-X syndrome, which results from mutations of the *XH2* gene, located on the long arm of the X chromosome (Xq13.3). This gene regulates  $\alpha$ -globin gene expression. The ATR-X syndrome is characterized by the presence of severe intellectual disability, minor facial anomalies, genital anomalies, and a mild form of Hb H disease.

## **$\beta$ -Thalassemia**

### **Definitions and Clinical Manifestations**

$\beta$ -Thalassemia is caused by a decrease in production of  $\beta$ -globin chains as a result of mutations in the  $\beta$ -globin gene. Approximately 200 point mutations (or, rarely, deletions) are known to cause this disease. The clinical presentation is variable because the mutations cause a variable impairment of  $\beta$ -globin synthesis. The  $\beta$ -thalassemias are prevalent throughout the Mediterranean region, Africa, the Middle East, the Indian subcontinent, Burma, Southeast Asia (including the Malay Peninsula), southern China, and Indonesia. The high frequency of occurrence in the tropics reflects a survival advantage of heterozygotes against *Plasmodium falciparum* malaria. (This is also true with  $\alpha$ -thalassemia.)

### **Clinical Forms**

Inheritance of 1 gene for  $\beta$ -thalassemia results in  $\beta$ -thalassemia trait (also called thalassemia minor). This condition can be diagnosed by simple screening for microcytosis and a high RBC count. The more severe forms of  $\beta$ -thalassemia result from homozygosity or compound heterozygosity for the mutant  $\beta$ -globin allele and result in thalassemia major or in thalassemia intermedia.  $\beta$ -Thalassemia major is characterized by early onset of anemia, characteristic blood changes, and high Hb F and Hb A<sub>2</sub>. Patients with thalassemia major show clinical symptoms in the first year of life and require regular transfusions for survival; those with thalassemia intermedia will exhibit symptoms later in life and will also need intermittent transfusions. The anemia in thalassemia intermedia is well

compensated and may be exacerbated by infection, folate deficiency, or increasing hypersplenism.

Population screening has been effectively carried out with the naked-eye single-tube RBC osmotic fragility test (NESTROFT). Although NESTROFT is not highly specific, it is highly sensitive, with few false-negative findings. It is relatively inexpensive and simple, and thus suited to large-scale population screening for thalassemia trait. Genetic counseling for couples at risk for offspring with homozygous  $\beta$ -thalassemia may be aided by NESTROFT.

### **Pathophysiologic Features and Clinical Manifestations of Thalassemia Major**

Severe  $\beta$ -thalassemia produces clinical features in the first year of life as a result of a decline in Hb F synthesis without concomitant increase in Hb A. The decreased  $\beta$ -globin synthesis in this condition results in an excess of  $\alpha$  globins, some of which are used for synthesis of other hemoglobins that do not have  $\beta$  chains, such as Hb F ( $\alpha_2\gamma_2$ ) or Hb A<sub>2</sub> ( $\alpha_2\delta_2$ ), which are then increased. Free  $\alpha$  chains left over form tetramers, which are insoluble; they accumulate and precipitate within the RBC, leading to increased fragility and cell death. The RBC life span is thus shortened, and RBCs may be destroyed within the marrow, leading to ineffective erythropoiesis, which is the hallmark of  $\beta$ -thalassemia. The lack of  $\beta$  chains leads to decreased hemoglobin content per cell, hypochromia, and microcytosis. Attempts to increase the RBC mass result in expanded marrow cavities and extramedullary erythropoiesis in the liver and spleen.

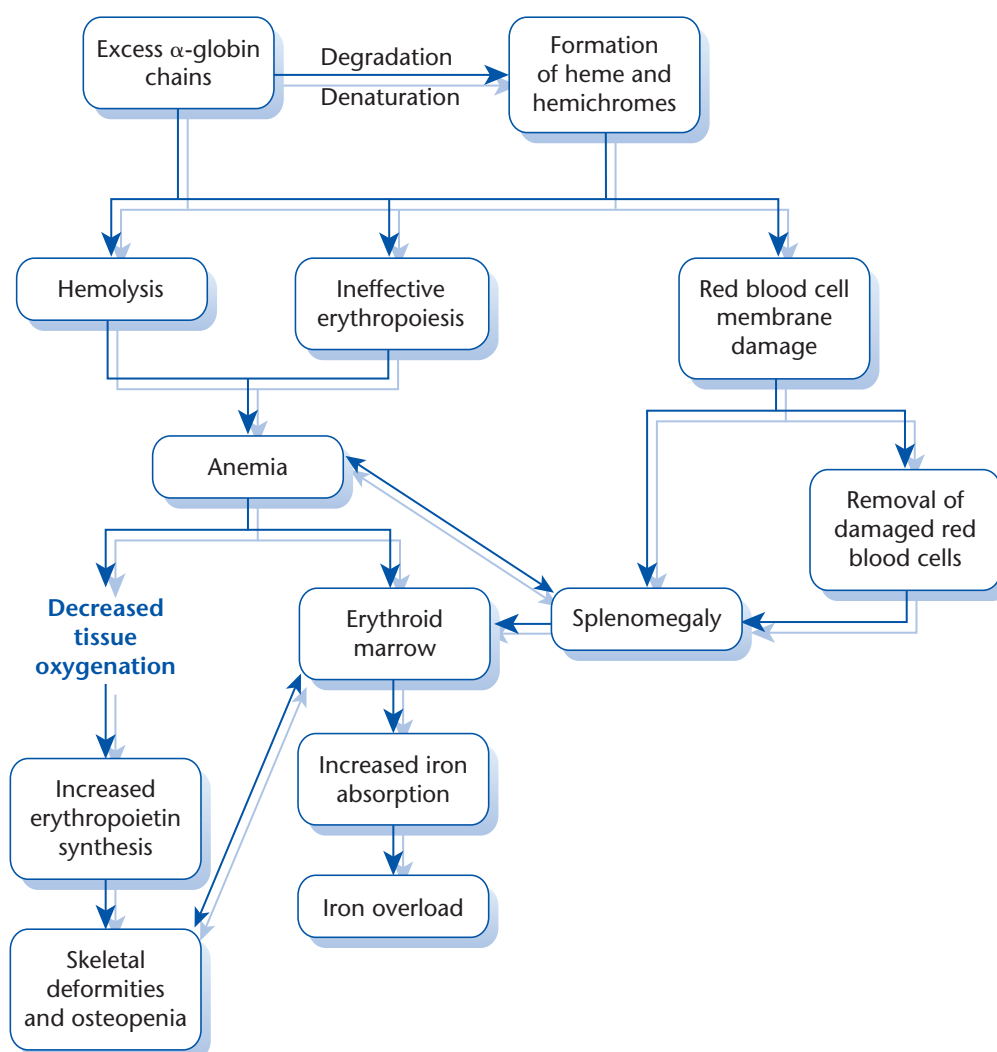

Children with thalassemia major exhibit symptoms at approximately 6 months of age with anemia that can be severe and symptomatic. Growth failure, cardiac dysfunction, pallor, jaundice, and hepatosplenomegaly are commonly seen. The bodies of these patients become loaded with iron, even when transfusions are sparingly given, because of increased iron absorption from the diet. Iron toxicity affects the liver (leading to cirrhosis), pituitary (leading to hypogonadism and growth failure), heart (leading to arrhythmia and cardiomyopathy), and bone (leading to pathologic fractures) (Figure 262-1).

### **Management**

Blood transfusions are provided to correct anemia, suppress erythropoiesis, prevent growth failure, and inhibit increased gastrointestinal absorption of iron. Splenectomy is usually performed when hypersplenism occurs and transfusion requirements increase.

Folic acid supplementation may be needed to meet the needs of increased RBC production. Iron chelation therapy is indicated when iron accumulation is seen following repeated RBC transfusions. Deferoxamine given as a daily 8-hour subcutaneous infusion through small portable pumps has been used since 1977 and is well tolerated and extremely effective. The oral iron chelator, deferasirox, was approved by the US Food and Drug Administration in November 2006. Deferasirox is much less cumbersome for patients and has had similar efficacy as deferoxamine in preclinical trials. The dose is 20 to 30 mg/kg/day, depending on the degree of iron overload, renal function, and

**Figure 262-1** Effect of excess free  $\alpha$ -globin chain production.

response to medication. Toxicities include proteinuria and elevation of creatinine, chemical hepatitis, or transaminase elevation. These toxicities usually respond to dose decreases of 10 mg/kg/day. Children with sickle cell disease have low creatinine, and rises in serum creatinine with toxicity may not reach levels above the normal for age; thus, increases of 30% over baseline should prompt dose decreases for such patients. Annual audiologic and ophthalmologic examinations, as well as echocardiographic examinations, are indicated for all chelation regimens to monitor for drug and iron toxicity. Chelation should be interrupted for serum ferritin levels of 500 ng/mL or less because of increased drug toxicity at low ferritin levels. Another oral chelator, deferiprone, may be used for chelation, although dose-related side effects such as neutropenia, arthropathy, agranulocytosis, and possibly hepatic fibrosis have been reported. This drug has been recently licensed in the United States for thalassemia only.

Clinically, treatment effectiveness is measured by monitoring the serum ferritin level, even though this

method is not the most accurate measure of total body iron stores. Ferritin levels lower than 2,500 mg/dL are associated with improved cardiac disease-free survival. Measurement of hepatic iron stores provides a quantitative, specific, and sensitive method for evaluating the body's iron burden, but this requires an invasive liver biopsy. Magnetic susceptometry provides a noninvasive method for measuring hepatic iron stores and has become increasingly available in many centers in the developed world, but still may not be easily available in low-income countries.

Hematopoietic stem cell transplantation may be performed in cases in which chronic transfusions and chelation are not possible. Transplantation, if successful, reverses the need for transfusions or chelation therapy, but it carries the risk for serious adverse effects such as graft failure, rejection, graft-versus-host disease, and death. In addition, preexisting and established growth failure, endocrinopathies, and gonadal dysfunction are not reversed. The availability of supportive care after transplantation must also be taken into consideration.

In the right setting, the use of either related or unrelated human leukocyte antigen (HLA)-matched donors results in excellent outcomes for low-risk patients who do not have preexisting severe organ damage.

## STRUCTURAL HEMOGLOBINOPATHIES

Structural hemoglobinopathies usually result from a point mutation in the  $\alpha$ - or  $\beta$ -globin gene, which produces an erroneous amino acid insertion in the polypeptide chain of the hemoglobin molecule. This results in a functional abnormality, the effects of which depend on where the missense mutation occurs. The mutation might result in the following effects: no physiologic abnormality and no clinical problem, an increased tendency to aggregate (Hb S, Hb C), an instability of the hemoglobin molecule resulting in a hemolytic anemia (Hb Zurich), increased oxygen affinity (Hb Bethesda), decreased oxygen affinity (Hb Kansas), and decreased oxygen-carrying capacity (Hb M).

More than 400 different abnormal hemoglobins have been described to date, but most are rare and cause no clinical disease. Sick cell disease is a frequent and clinically relevant structural hemoglobinopathy.

## Sickling Disorders

Sickling disorders depend on gene interactions. SS, known as sickle cell anemia, indicates homozygosity for the mutant Hb S, which results in no normal  $\beta$  alleles and, therefore, no Hb A. Hemoglobin SC disease indicates double heterozygosity for 2  $\beta$ -chain mutants, Hb S and Hb C, which results in no normal  $\beta$  alleles and, therefore, no Hb A. Sick  $\beta$ -thalassemia results from double heterozygosity for Hb S and  $\beta$ -thalassemia. In this disorder, 1  $\beta$  gene directs the synthesis of Hb S, and the other is either completely suppressed, and the patient has no Hb A (S  $\beta^0$ -thalassemia), or incompletely suppressed, and the patient produces a small amount of Hb A (S  $\beta^+$ -thalassemia). Hb A<sub>2</sub> is increased in the sickle  $\beta$ -thalassemia conditions and can be mildly elevated in Hb SS.

Finally, SO Arab and SD indicate double heterozygosity for Hb S and Hb O or D, respectively. Both of these conditions can have clinical phenotypes similar to Hb SS disease. Coinheritance of hemoglobins S and E, on the other hand, does not result in an abnormal phenotype, and individuals have a mild hypochromia, but are otherwise healthy.

In hereditary persistence of fetal Hb with Hb S, a failure to switch from  $\gamma$ - to  $\beta$ -chain synthesis is coinherited with Hb S. Patients have high levels of Hb F. Their clinical symptoms are mild because of the protective effects of Hb F.

## Pathophysiology of the Sickling Phenomenon

In its deoxygenated state, Hb S is extremely insoluble. Polymer formation within the RBC causes a shape change to the sickled form that gives the disease its name. Sickling is accompanied by increased rigidity, loss of deformability, increased adhesiveness to endothelial cells, and RBC membrane damage, all of which adversely affect the flow properties of the RBCs through the microvasculature. This produces vaso-occlusion, which sets up a vicious

cycle of stasis, low oxygen pressure in tissues, tissue acidosis, increased viscosity, further polymer formation, and more vaso-occlusion to complete and perpetuate the cycle. Membrane damage causes the RBC life span to be short (15 days instead of 120 days), resulting in a hemolytic anemia. Endothelial damage from vaso-occlusion also results in a hypercoagulable state that promotes sluggish circulation in the microvasculature.

## Clinical Manifestations

All of the sickling disorders mentioned previously are associated with similar clinical features; the heterozygous state resulting in Hb S trait (AS pattern) is generally asymptomatic except for painless hematuria in adults and complications during strenuous exercise with dehydration or at high altitudes. However, Hb S  $\beta^0$ -thalassemia is a double heterozygous condition may result in a disease as severe as Hb SS disease.

Hemolytic anemia results in pallor, jaundice, increased fatigue, gallstones, and poor growth. Aplastic crises occur after viral infections (parvovirus B19 most often implicated), in which even with transient viral marrow suppression, life-threatening drops in hemoglobin levels occur.

Vascular obstruction from intravascular sickling results in episodic, variable, and unpredictable musculoskeletal pain. This pain can be disabling if frequent and severe, although these so-called pain crises are usually uncomplicated and not life-threatening. Acute bone pain or infarction is common at all ages. Dactylitis, a swelling of the hands and feet, is a classic early childhood symptom. Osteonecrosis of the spine and femoral heads is often seen in adults; this commonly causes chronic pain. Splenic sequestration crisis may occur. This sudden pooling of blood in the spleen with hypovolemic shock is life-threatening and may recur during early childhood. Stroke, although uncommon, is recurrent if not treated appropriately with long-term blood transfusions after it occurs. In addition, a variety of cerebrovascular catastrophes, such as hemorrhage, can occur. Acute chest syndrome—pulmonary infarction or pneumonia (or both)—is common. Beginning in early childhood, the risk for severe bacterial infections with encapsulated organisms is lifelong, and such infections are a common cause of death. This is caused by the loss of splenic function (autosplenectomy) from recurrent vaso-occlusion and fibrosis. Renal manifestations include the loss of urine concentration capacity caused by sickling in vessels around the loop of Henle; large volumes of dilute urine are produced even in young children, underscoring the need for copious fluid intake to avoid dehydration. Further renal problems include hematuria and glomerular nephropathy. Other manifestations of vaso-occlusion include priapism, trophic leg ulcers, and blindness from retinopathy.

The disease is extremely variable in its severity. Factors that affect disease severity have not been clearly defined and remain the subject of research. Data suggest that factors influencing severity include genetic markers such as the  $\beta$ -globin gene haplotype, coinheritance of  $\alpha$ -thalassemia (beneficial), and the

amount and distribution of Hb F (higher levels are beneficial).

Sickle Cell Trait

Sickle cell trait is a benign carrier state, and most people have no clinical symptoms. The incidence of the trait in blacks varies from 6.7% to 10.1%. Sickle cell trait can cause hematuria and a loss of urine concentration capacity. Symptoms from intravascular sickling have been reported with strenuous exercise at high altitudes or without proper hydration and with flying at high altitudes in unpressurized aircraft.

Diagnosis

In most of the developed countries, including the United States, the diagnosis of sickle cell disease is established through the newborn screening program. Hemoglobin is separated from dried blood spots collected from infants in the newborn nursery and allows for the early identification of affected infants before the onset of clinical manifestations. In older patients in whom the diagnosis of sickle cell disease is suspected and who may have been born before the initiation of the newborn screening program or who were born outside the United States, their clinical history and physical examination are the first steps to diagnosing a sickling disorder.

The presence of Hb S is evaluated by the solubility test, which is inexpensive and sensitive to the carrier state, but does not distinguish trait from the disease. Hemoglobin electrophoresis confirms the exact genotype. Finally, the presence of hemolytic anemia (low hemoglobin, high reticulocyte counts, increased bilirubin, and lactic dehydrogenase) and morphologic sickling can be assessed by blood smears.

Management

Management consists of symptomatic and supportive care of complications such as treating pain episodes with analgesics (often opioids), placing local heat packs, ensuring adequate hydration, adjusting the acid-base balance, preventing hypoxia, avoiding exposure to cold, and treating febrile episodes early and aggressively with antibiotics.

Judicious use of blood transfusions will help prevent strokes in children. Elevated time-averaged mean velocity in the middle cerebral and distal internal carotid arteries on screening transcranial Doppler (TCD) has been shown to be associated with a high risk for overt stroke in patients with Hb SS. Thus, TCD screening and chronic blood transfusions for abnormal TCD results is now recommended. In 1995, the Stroke Prevention Trial in Sickle Cell Anemia (STOP) trial was conducted as a multicenter randomized trial to determine the efficacy of transfusion therapy for preventing strokes in patients with abnormal TCD. This intervention was extremely effective, and is now the standard of care for screening children younger than 16 years and for beginning chronic transfusions for elevated TCD.

Blood transfusions also help correct severe anemia (Hb <5 g/dL) from aplastic crises or splenic

sequestration and may also be of benefit in complicated pregnancies. Preoperative blood transfusion for invasive surgery with prolonged anesthesia is useful to avoid intraoperative and postoperative complications.

Management is optimized by early diagnosis with screening of newborns. Routine daily prophylactic penicillin and pneumococcal vaccine are used to prevent the high childhood mortality from infections.

Psychosocial support and self-help groups are important for improved disease adjustment, especially for adults. Pain attacks are often capricious, severe, and frequent. They can be a barrier to self-determination and independent living.

Recent advances have brought research strategies to the bedside. Agents that stimulate fetal hemoglobin production, such as hydroxyurea, have proved useful in preventing much of the morbidity of the disease. Peripheral or cord blood stem cell transplantation from an HLA-identical sibling, although a high-risk procedure, is curative. Stem cell transplantation is used for certain individuals with markers for adverse outcome, such as stroke in a young child, or severe and recurrent acute chest syndrome that has been associated with later pulmonary hypertension and early mortality. Finally, antisickling agents, such as membrane-active drugs, anticoagulants, and gene therapy, are being investigated as approaches of the future.

Rare Structural Hemoglobinopathies

Table 262-2 lists the rare structural hemoglobinopathies and their prototypes.

Unstable Hemoglobins

Unstable hemoglobins usually result from amino acid substitutions near the heme pocket. The instability causes a tendency of the heme to separate from the globin chain with the slightest oxidative stress. The denatured hemoglobin precipitates in the RBC and forms Heinz bodies, which cause the cells to sequester in the spleen, and a hemolytic anemia results.

Diagnosis is by demonstration of a hemolytic anemia, detection of Heinz bodies by staining, and the heat precipitation test. Hemoglobin electrophoresis is not always useful because of the tendency of the hemoglobin to rapidly denature.

Table 262-2 Rare Structural Hemoglobinopathies and Their Prototypes	
HEMOGLOBINOPATHY	PROTOTYPE
Unstable hemoglobins	Hb Zurich
Hemoglobins with high oxygen affinity	Hb Bethesda
Hemoglobins with low oxygen affinity	Hb Kansas
Hemoglobin M prototype	Hb M Boston

Hb, hemoglobin.

Management includes avoiding oxidant drugs, providing transfusions as clinically indicated, and removing the spleen if anemia is severe.

### **Hemoglobins With High Oxygen Affinity**

In hemoglobins with high oxygen affinity, the amino acid substitution is near the  $\alpha_1$ - $\beta_2$  interface, resulting in a tight binding of oxygen. Release of oxygen to tissues is slow, resulting in inefficient tissue oxygenation. The end result is increased hemoglobin production caused by high erythropoietin levels.

Diagnosis is made by the presence of familial erythrocytosis (polycythemia), exclusion of other causes of polycythemia (eg, polycythemia vera, cyanotic heart disease), high RBC mass, high arterial oxygen saturation, and a markedly left-shifted oxygen dissociation curve.

Management consists of maintaining hematocrit levels at 70% by phlebotomy to prevent high viscosity.

### **Hemoglobins With Low Oxygen Affinity**

In hemoglobins with low oxygen affinity, the amino acid substitution is also near the  $\alpha_1$ - $\beta_2$  interface. The hemoglobin picks up oxygen poorly from the lungs, and high deoxyhemoglobin levels result, causing cyanosis.

Diagnosis is made by the oxygen-dissociation curve, which is right shifted. The hemoglobin level and RBC mass are normal.

No specific management is necessary or effective. The cyanosis is relatively well tolerated if strenuous activities are avoided.

### **Hemoglobin M**

In Hb M, the amino acid substitution is near the heme pocket, close to the site of the iron (Fe) molecule. The mutant hemoglobin loses its ability to keep the Fe in its ferrous state, and the hemoglobin is constantly in the methemoglobin state,  $\text{Fe}^{3+}$ , and is unable to carry oxygen. Chronic cyanosis results.

Diagnosis is made by history of cyanosis since birth, with a normal oxygen saturation; by brown discoloration of freshly drawn blood, which does not change with aeration; and by spectrophotometry to confirm presence of methemoglobin. Electrophoresis also demonstrates the abnormal hemoglobin.

No management is needed because the amount of Hb M is insufficient to cause physiologic derangements.

### **Hemoglobin C, D, and E**

Structural variant hemoglobins are synthesized at a lower rate than normal  $\beta$  chains and comprise less than one-half the total hemoglobin in heterozygotes. Heterozygous Hb C (AC) results in mild target cells, but no anemia. Homozygous C (CC) produces a mild hemolytic anemia, marked RBC morphologic changes (target cells, hemoglobin crystals, and microspherocytes), and mild splenomegaly. Heterozygous E (AE) causes a mild thalassemic phenotype with mild microcytosis and hypochromia. Homozygous E (EE) results in a moderate thalassemic phenotype with hypochromia, microcytosis, and mild anemia. A combined E- and  $\beta$ -thalassemia inheritance results in a transfusion-dependent thalassemic phenotype. Hb E is common in Southeast Asia and in certain areas of the Indian subcontinent.

## **TECHNOLOGICAL ADVANCES**

### **Reproductive Options for Carriers of Hemoglobinopathy**

Prenatal screening and genetic counseling are now readily available and are good ways to provide reproductive options for couples at risk for having children with hemoglobinopathies. Nondirective genetic counseling should be provided and targeted to populations with a high prevalence of the hemoglobinopathy traits.

Prenatal diagnosis can be performed by chorionic villus sampling. Challenges include technical difficulties of the various methods used, as well as their expense. Furthermore, for safety and effectiveness, women with at-risk pregnancies must be assessed for prenatal diagnosis, ideally in the first trimester (8 to 14 weeks' gestation). This process requires awareness in communities with a high prevalence of the genetic defect. The choice of therapeutic abortion for involved pregnancies can be difficult depending on cultural and religious beliefs. Research studies report a higher acceptance of prenatal diagnosis if another child is affected.

Preconception diagnosis and implantation of normal embryos after in vitro fertilization is an alternative that is currently available in the West. It is extremely expensive and cannot be performed routinely.

In utero therapy that uses stem cell transplantation is an interesting and potentially exciting technology that would help at-risk couples that do not opt for termination. It allows for the relatively non-immunocompetent fetus to accept the stem cell transplant more easily without experiencing graft rejection and graft-versus-host disease. This therapy is currently in early research trials.

### **Improvements in Transfusion Safety**

The mainstay of care for children with hemoglobinopathies continues to be blood transfusion support. Transfusion safety is thus an important consideration, particularly the prevention of transfusion-transmitted infections. Donors should be screened for hepatitis B and C, human immunodeficiency virus, syphilis, and malaria. Donor screening may sometimes be ineffective because of insensitive tests, expired kits and reagents, and improper procedures, particularly in low-income countries. Transfusion-transmitted infections remain a risk.

### **Stem Cell Transplantation**

Improved techniques of stem cell transplantation that use HLA-matched sibling donors may cure hemoglobinopathies. Nonmyeloablative or reduced-intensity myeloablative stem cell transplantation, which has reduced morbidity, but leads to a chimerism in the recipient, is being explored as an investigational procedure. Gene therapy is now in early trials.

Simple awareness of genetic diseases and education and counseling of families at risk are crucial to avoiding the burden of these diseases, both to individuals and to society.

**WHEN TO REFER**

- All patients with thalassemia intermedia and thalassemia major should be followed by a hematologist.
- All children with sickle hemoglobinopathies, regardless of whether the child has experienced serious complications of sickle cell disease, should be regularly followed by a hematologist.
- Referral should occur immediately after a positive newborn screening result is returned.
- Serious complications can include stroke, splenic sequestration, and recurrent acute chest syndrome.
- Pregnant patients should be referred for care during pregnancy.

**WHEN TO ADMIT**

- Anemic crisis (Hb <5 g/dL or hemodynamic compromise)
- Sudden splenic enlargement
- Pain not responding to home opioids
- Difficulty breathing, chest pain
- Fever spikes (>38°C [100.4°F] core, repeated in 30 minutes)
- Any central nervous system symptoms

**Chapter 263****HEMOLYTIC-UREMIC SYNDROME**

Horacio Esteban Adroque, MD; Joseph Angelo, MD

**INTRODUCTION**

Hemolytic-uremic syndrome (HUS) is a systemic thrombotic microangiopathy clinically defined by the classic triad of nonimmune microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney injury. The underlying pathologic process in HUS results in vascular endothelial injury leading to arteriolar-capillary occlusive lesions formed by platelet-fibrin thrombi. While the kidney is the most common and clinically significant site of injury, multiple organ systems including the central nervous system, gastrointestinal tract, heart, lungs, and pancreas can be affected. Broadly, HUS is categorized into 2 types. HUS that follows diarrheal illness or is related to specific infectious agents is designated as typical or D+ HUS, while atypical HUS (aHUS) is most commonly caused by genetic mutations in the complement cascade. Overall, typical HUS is much more common than aHUS, and most of these cases are related to infection by Shiga toxin-producing enterohemorrhagic *Escherichia coli* (EHEC). In addition, typical HUS tends to be self-limited and less severe than genetic forms of HUS. Genetic forms have a longer, potentially recurrent course and more frequently lead to chronic kidney disease. Of note, increased understanding of the pathophysiology of HUS and the availability of tests for genetic causes has led to classification schemes based on the specific etiology of HUS.

## ETIOLOGY AND PATHOGENESIS

### HUS Related to Shiga toxin

HUS is the most serious complication resulting from EHEC infection. The Shiga toxin (ST) produced by EHECs is structurally similar to toxins produced by other gram-negative organisms, including *Shigella dysenteriae*, and is also called verotoxin because of its ability to kill vero cells in culture. ST is released into the gastrointestinal tract, translocates across the intestinal epithelium, and enters the systemic circulation. The translocation of ST across the GI epithelium is promoted by intimin, a protein that helps with bacterial adherence to the epithelial cells, and the receptor Tir, which promotes ST entrance in the cell. Once ST enters the systemic circulation, it binds its target globotriaosylceramide (GB3) on the surface of host cells, including the glomerular endothelium. The classic view of STs is that once they are internalized by endothelial cells they lead to cellular apoptosis through the inactivation of ribosomes and, therefore, the inhibition of protein synthesis. While this is one mechanism of endothelial damage produced by STs, there is also evidence that the ability of STs to alter endothelial cell gene expression leads to a change in endothelial phenotype, which transforms the endothelium from its normal state into a proadhesive, prothrombotic, and inflammatory surface. These changes underlie the microangiopathic process that is a hallmark of HUS.

### HUS Related to Gene Mutations

HUS related to genetic mutations falls under the broader category of aHUS, which can also include forms of thrombotic microangiopathy (TMA) related to systemic illnesses such as pregnancy-associated HUS, hemolysis/elevated liver enzymes/low platelet count (HELLP) syndrome, and drug-related HUS. While similar pathologically and clinically to typical HUS, the underlying etiology of genetic forms of HUS are related to the dysregulation of the complement system. Thrombotic thrombocytopenic purpura (TTP) is another form of TMA related to HUS and is secondary to the loss of activity of ADAMTS-13, a protein which cleaves large multimers of von Willebrand factor. The loss of ADAMTS-13 activity can trigger a systemic TMA.

Several complement pathway mutations have been associated with HUS. Complement factor H (CFH) is a plasma protein that acts as a cofactor to complement factor I (CFI) in regulating the alternative complement pathway by promoting the dissociation of C3 convertase and also competes with complement factor B for C3b recognition. In addition to genetic mutations in CFH, inactivation of CFH by antibodies has been described in children with aHUS. CFI works together with CFH to cleave C3b and C4b. CFI mutations can affect 4% to 10% of patients with aHUS.

Mutations in another CFI cofactor, membrane cofactor protein (MCP), have been described in 10% to 15% of children with aHUS. MCP works with CFI to cleave C3b and C4b on cell surfaces, providing a protective effect on the glomerular endothelium.

Gain-of-function mutations in complement proteins have also been associated with aHUS. These include complement factor B (CFB) and C3. CFB mutations result in chronic alternative pathway activation in which C3 convertase hyperactivity results in enhanced C3b formation. Similarly, mutations in C3 reduce C3b binding to CFH and MCP, impairing the degradation of C3b.

More recently, there have been reports of noncomplement-related gene mutations, such as diacylglycerol kinase  $\epsilon$ , related to aHUS.

## EPIDEMIOLOGY

HUS is a common cause of renal failure in children, with most cases occurring in children younger than 5 years. Up to 90% of cases are of the typical HUS type, and 10% are aHUS. In the United States and Europe, *E coli* 0157:H7 is the most commonly implicated ST-producing organism causing typical HUS. However, other strains of *E coli* and *Streptococcus pneumoniae* have also been associated with outbreaks of HUS.

## CLINICAL PICTURE

An infection with one of the common causative agents of HUS typically starts with the development of watery diarrhea following an incubation period of 3 to 8 days. Watery diarrhea is then followed by bloody diarrhea, abdominal cramping, and nausea and vomiting in 50% of children. Fever is present in approximately 30% of children. These symptoms precede the development of more systemic symptoms such as malaise and pallor. Renal manifestations appear around the same time and are marked by the development of acute kidney injury, which is oligo-anuric. Hypertension develops in approximately 50% of children with HUS and is the result of fluid retention and edema in the acute phase. The hypertension may persist as chronic hypertension in the long term. While the kidney and GI tract are the most common systems affected, as many as 30% of children can have central nervous system involvement manifesting as lethargy, seizures, and sometimes cerebral edema and coma. Other organ systems involved include the pancreas and myocardium.

Laboratory studies reflect the underlying pathology of HUS and show anemia, thrombocytopenia, high levels of lactate dehydrogenase, low haptoglobin, and the presence of fragmented erythrocytes (schistocytes) on peripheral blood smear. The onset of renal involvement is evidenced by hematuria, red blood cell casts on urine microscopy, proteinuria, and elevated serum creatinine. Other laboratory abnormalities reflect damage to extrarenal organs such as elevated pancreatic enzymes and troponin levels.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis is wide and includes acute poststreptococcal glomerulonephritis, TTP, systemic lupus erythematosus, Henoch-Schönlein purpura, disseminated intravascular coagulation, sepsis, intussusception, and renal vein thrombosis. A major distinguishing feature of HUS is the presence of schistocytes on the peripheral blood smear. Renal vein thrombosis can be discerned by renal ultrasound, typically with

unilateral renal enlargement compared to HUS in which both kidneys are enlarged.

## MANAGEMENT

The management of HUS is similar to the therapy provided for children with acute kidney injury from other causes, with additional attention to those issues specific to HUS. The management of the electrolyte, acid-base, and volume overload associated with HUS continues to be based on medical management. Because of the potential need for initial fluid resuscitation and the deleterious effects of fluid overload, particularly in critically ill patients, strict attention to volume management is required. Patients without anuria can be treated early with loop diuretics. For those patients with anuria, the use of acute dialysis with hemodialysis, peritoneal dialysis, or continuous renal replacement therapy has contributed significantly to reducing the mortality rate from as high as 50% to between 3% and 5%. Two-thirds of children with HUS require acute dialysis, while the other one-third develop some degree of renal insufficiency.

In addition to aggressively managing the renal sequelae of HUS, specific attention must also be paid to the other affected organ systems. The use of antibiotics to treat typical HUS is controversial. While some studies have shown benefit from the use of antibiotics in HUS, several others have demonstrated not only a lack of benefit but also a potential for harm. No clear benefit has been demonstrated for the use of antibiotics in children in the acute phase of HUS, and their use is not currently recommended.

The use of antimotility agents is contraindicated in children with HUS. Although helpful with the symptomatic treatment of diarrhea, their use increases the risk of developing toxic megacolon in the setting of typical HUS.

As with antibiotics, the evidence for the use of plasma exchange in the treatment of typical HUS has not been definitive. However, some data support the use of plasma infusion or plasma exchange in this setting. Therefore, children who have a significant worsening of disease, such as severe renal failure, heart failure, or neurologic symptoms, should be considered for plasma therapy. Plasma therapy is contraindicated in children with HUS associated with *S pneumoniae*, because plasma contains preformed antibodies to the Thomsen-Friedenreich antigen and thus, can worsen the disease process.

While the response to plasma therapy in children with aHUS may vary depending on the underlying mutation causing the disease, the overall use of plasma exchange in children with aHUS has been shown to decrease mortality. A suggested regimen is the initiation of plasma exchange within 24 hours of disease onset using the exchange of 1 to 2 volumes/day or infusion of approximately 20 to 30 mL/kg body weight. Decisions regarding the initiation and continuation of plasma therapy should be made following consultation with a pediatric subspecialist experienced in the treatment of aHUS.

Thrombotic microangiopathies fall along a spectrum, and there can be overlap between HUS and TTP. TTP is defined by the 3 criteria of HUS (MAHA,

thrombocytopenia, and acute kidney injury) plus neurologic signs and fever. While there is renal impairment in patients with TTP, it usually is not the prominent feature and the patients rarely require dialysis. However, as both entities can present similarly, the differentiation is not always clear. Therefore, for those presenting with severe multisystem failure, plasma exchange should be initiated early.

More recently, the use of an anti-C5 monoclonal antibody, eculizumab, has shown benefit in the treatment of aHUS. While the reports demonstrated the termination of the microangiopathic process in HUS, some variability exists in these reports with respect to the prevention of the long-term consequences of HUS, including improvement in renal function. However, a recently published report of phase 2 trials of eculizumab in a more chronic setting did show improvement in the estimated glomerular filtration rate over the course of the trial, with earlier use showing the most significant result. Owing to an increased risk of meningococcal infection, children receiving eculizumab should receive meningococcal vaccination before or as soon as possible after starting treatment and should receive antibiotic prophylaxis against meningococcal infection.

The management of the hematologic effects of HUS should be performed cautiously and with close attention to the development of volume overload and pulmonary edema. Packed red blood cell infusions should be limited to cases when the hemoglobin is rapidly downtrending or the patient is having clinical changes related to anemia. The treatment of thrombocytopenia should also be limited because this may worsen the development of microthrombi in HUS. The indications for platelet transfusion are active bleeding or need for surgical procedures. To prevent further volume overload, the use of diuretic therapy in conjunction with blood product infusions is an important consideration.

## PROGNOSIS AND LONG-TERM SEQUELAE

With improvements in critical care and dialysis therapies, mortality rates in children with typical HUS now range between 3% and 5%, with mortality typically resulting from more severe and widespread effects on multiple organ systems. With better survival rates during the acute phase of HUS, long-term sequelae have become more clear. From a renal standpoint, one study showed that following acute HUS, 39% of 61 children had a risk of developing long-term complications including hypertension, proteinuria, and chronic or end-stage renal disease. Similarly, a meta-analysis showed that death or end-stage renal disease occurred in 12% of children with typical HUS, and that 25% of survivors had some long-term renal complications. In addition, histologic studies have shown an increased risk of developing chronic changes such as glomerulosclerosis and interstitial fibrosis following an episode of HUS. A notable finding is that the duration of oligo-anuria is a predictor of the occurrence of late complications following HUS. The high likelihood of long-term renal dysfunction in children

following HUS demonstrates the need for regular follow-up with a nephrologist to monitor parameters such as hypertension, proteinuria, growth, and progression of chronic kidney disease. The treatment of hypertension and proteinuria with angiotensin converting enzyme inhibitors is prudent in helping to reduce the further worsening of renal damage in the chronic setting.

## KIDNEY TRANSPLANTATION AFTER HUS

Children who progress to end stage renal disease following typical HUS are not at an increased risk of graft failure when compared to those patients without HUS. In contrast, children with HUS related to genetic mutations have a high rate of HUS recurrence in the kidney graft, up to 60% in one study, and an adult HUS study demonstrated that this recurrence is an independent risk factor for graft loss. The risk of HUS recurrence and graft loss can vary depending on the underlying genetic defect. For example, patients with defects in membrane-bound proteins, such as MCP, tend to have a lower risk of HUS recurrence in the transplanted kidney compared to those with circulating factor defects such as CFH and CFI. Some caution must be used in assessing these circumstances because a subset of patients with defective MCP can have combined errors in both MCP and also circulating factors. Given this variability in the risk of recurrence and the availability of existing and emerging treatment strategies, kidney transplantation in those patients with genetic forms of HUS should be a case-by-case consideration rather than an absolute contraindication in all cases. Along these lines, both plasma therapy and more recently eculizumab have shown some success in reducing the risk of post-transplant recurrence in those patients with genetic forms of HUS.

## CONCLUSION

Since the original description of HUS by Gasser et al in 1955, much has been learned about the etiology, pathophysiology, and treatment of children with HUS. Improvements have been made in the acute care of these patients, which has lowered their mortality rates. More recently, longer-term therapies have been used to treat those children with genetic defects underlying their HUS. Continued work on methods of prevention and treatment should produce further improvements in both acute and chronic outcomes related to HUS.

### WHEN TO REFER

- All patients with HUS should be referred to a pediatric nephrologist or pediatric hematologist as indicated.

### WHEN TO ADMIT

- All patients with HUS must be admitted.

## Chapter 264

# HENOCHE-SCHÖNLEIN PURPURA

Horacio Esteban Adrogué, MD; Nicole Hayde, MD, MS

Henoch-Schönlein purpura (HSP) is the most common form of vasculitis in children. This small-vessel vasculitis is mediated by immunoglobulin A (IgA)-containing immune complexes and is characterized by nonthrombocytopenic purpura, abdominal pain, arthralgias, and renal disease. The diagnostic criteria published in 1990 by the American College of Rheumatology include palpable purpura, initial presentation at 20 years or younger, bowel angina, and typical biopsy findings. If 2 or more diagnostic criteria are present, then the sensitivity and specificity for the diagnosis of HSP are greater than 87%.

## EPIDEMIOLOGIC FACTORS

HSP is more common in Europe and Asia than it is in the United States, with an estimated annual incidence in the United Kingdom of 20:100,000 children. White children have the highest incidence, and black children the lowest.

HSP mainly affects young children, with a peak incidence at 4 to 6 years of age. Unlike most vasculitides, HSP affects males more often than females, with a 1.5:1 male-to-female ratio. HSP seems to be more prevalent during the winter and spring, and in at least 30% of cases, an upper respiratory infection precedes the onset of symptoms. The seasonal distribution supports the hypothesis that infectious agents trigger the development of HSP. Other infections, drug allergies, insect bites, and vaccines can also precipitate HSP.

Cases have also been reported in children with C2 and C4 complement deficiencies.

Hereditary fever syndromes such as familial Mediterranean fever can also precipitate HSP.

### CLINICAL PRESENTATION

The classic presentation of HSP includes lower extremity purpura, arthritis, abdominal pain, and renal disease. Cutaneous manifestations are the most common clinical features of children with HSP. In 50% of children, a macular-petechial rash is present. This rash is symmetric, sometimes purpuric, localized predominantly in the extensor surface of the lower extremities, forearms, and buttocks, and tends to spare the trunk. These lesions tend to fade with time, but new lesions can recur up to 3 months after the initial presentation. Nonpitting edema of the scalp, hands, and feet may be present in 30% to 70% of young children.

Joint manifestations occur in 60% to 80% of children; the knees, ankles, wrists, and fingers are most commonly affected. The joints involved are usually tender and swollen, but these symptoms resolve without any residual deformity.

Gastrointestinal manifestations develop in 50% to 70% of children with HSP, with a higher incidence in children with renal involvement. Gastrointestinal manifestations may precede the purpura by up to 2 weeks in as many as 20% of children. Intermittent colicky abdominal pain, vomiting, or gastrointestinal bleeding are most common, and up to 5% of children develop complications such as intestinal infarction, perforation, or intussusception.

Although most children may have some histologic evidence of renal inflammation, only 20% to 60% will exhibit urinary abnormalities. Renal disease rarely precedes the onset of rash, and evidence of HSP nephritis usually coincides with or follows the cutaneous manifestations. It is usually present within 4 weeks of the onset of the joint or gastrointestinal manifestations. The spectrum of renal involvement in HSP is broad and may include microscopic hematuria (transient or persistent), macroscopic hematuria (initial or recurrent), proteinuria, nephritic syndrome, and nephritic-nephrotic syndrome. When mild, HSP nephritis tends to resolve without any particular intervention. However, 2% to 5% of children with renal involvement progress to end-stage renal disease. Abnormal creatinine clearance at 3 years after onset, and ultrastructural abnormalities in the renal biopsy are the most consistent predictors of poor renal prognosis.

While most children with long-term renal involvement present early, there is evidence that a small subset of children may develop progressive renal disease even after having a benign urinalysis at presentation.

Testicular swelling and tenderness may be present in up to 35% of male children with HSP. If this manifestation is present, a thorough evaluation is necessary to rule out testicular torsion. Other serious complications such as pulmonary hemorrhage and central nervous system involvement have also been described.

The mean duration of symptoms is 3 to 4 weeks and up to one-third of children have at least 1 recurrence.

### EVALUATION

The diagnosis of HSP is based on clinical findings. There are no laboratory tests specific for HSP and the measurement of serum IgA levels is not helpful in confirming the diagnosis or providing prognostic information.

Urinalysis is an excellent screening test for assessing renal involvement and should be performed at diagnosis and at least monthly for 6 months even if the prior urinalysis was negative. The measurement of blood pressure should also be done at diagnosis and at subsequent visits for at least 6 months even if previously normal, as elevated blood pressures are associated with renal involvement.

In children with abnormal urinary sediment or elevated blood pressure, kidney function should be measured. A renal biopsy is not indicated in all children with a diagnosis of HSP; however, it should be considered in children with significant proteinuria for more than 1 month, renal insufficiency, hypertension, or nephrotic syndrome.

In atypical presentations of HSP, physicians should consider sending complete blood count, coagulation studies, and complement levels to evaluate for other causes of the clinical findings.

### DIFFERENTIAL DIAGNOSIS

A pediatrician faced with a child with acute purpuric and petechial eruptions must first ensure that the differential diagnosis is kept broad. Differential diagnoses include, but are not limited to, acute bacterial infections (invasive meningococcal disease), Rocky Mountain spotted fever, toxic shock, enteroviral infections, endocarditis, idiopathic thrombocytopenic purpura, parvovirus B19, Kawasaki disease, and acute hepatitis A.

In a child who presents with palpable purpura, abdominal pain, arthritis/arthralgia, or renal involvement, HSP nephritis is the most likely diagnosis. However some children may present atypically. The diagnosis is especially difficult in the child who presents without the characteristic purpuric rash; other causes of arthritis/arthralgia, abdominal pain, and renal disease should be investigated in this scenario.

### TREATMENT AND PROGNOSIS

Once other diseases are ruled out and a diagnosis of HSP is established, supportive care is the most important first step. Children should be monitored by their pediatrician and referred to a specialist if they develop signs of renal involvement, GI involvement, significant joint involvement, or demonstrate an atypical presentation.

Careful attention to nutrition, volume status, vital signs (especially blood pressure), and urinalysis is the cornerstone of treatment for most children. Although specific therapy for HSP remains controversial, carefully selecting children who are to receive more than standard supportive care is critical.

Mild cases of HSP do not require treatment provided that urine monitoring is conducted to detect modifications in the clinical follow-up, primarily during the first 6 months of the rash.

Mild abdominal pain can be monitored; however, children with significant abdominal pain may require steroids, which are initially given in high doses followed by a slow taper.

Children who do not display any urinary abnormalities within 6 months of diagnosis rarely develop chronic kidney disease (CKD). Steroids and other immunosuppressants are not indicated for the prevention of urinary abnormalities. Children who display only isolated hematuria or proteinuria have a very low risk of developing CKD (1.6%); they should therefore receive supportive care only, and not more aggressive treatment. Children who have nephritic or nephrotic syndrome have a much higher risk of CKD (10%–19.5%) and thus merit serious consideration for aggressive therapy. Girls are at higher risk for CKD (2.5 times higher than their male counterparts) and will likely benefit more from therapy.

Long-term follow-up of 219 patients (83 children younger than 16 years and 136 adults) with biopsy-proven HSP nephritis found that 60% of the children and 72% of the adults were treated with steroids, and 14% of children and 22% of adults received immunosuppressants. When kidney function outcomes (doubling of serum creatinine and eventual need for dialysis) were examined, the use of steroids or immunosuppressants failed to show any protective advantage over supportive care. Seven percent of these children ended up on dialysis after a mean follow-up of 6.7 years. Girls are at higher risk of eventual dialysis. The use of steroids in children with HSP should be decided on an individual basis, and cases that are considered for steroid treatment should be referred to a nephrologist. Another study of 27 children with HSP nephritis treated with long-term immunosuppression over a 10-year period showed that despite long immunosuppression, children with high-grade HSP nephritis had persistent renal abnormalities on long-term follow-up.

Evidence suggests that steroids for children with extrarenal manifestations may be helpful. Ronkainen and colleagues conducted a randomized, double-blind, placebo-controlled trial of early steroid treatment and monitored patients for 6 months. Of the 171 patients, 84 were treated with prednisone and 87 received a placebo. The endpoints were renal involvement at 1, 3, and 6 months and healing of extrarenal symptoms. These researchers found that the use of prednisone (1 mg/kg/day for 2 weeks, with weaning over the subsequent 2 weeks) was effective in reducing the intensity of abdominal pain (pain score, 2.5 vs 4.8;  $P = .029$ ) and joint pain (4.6 vs 7.3;  $P = .030$ ). Prednisone did not prevent the development of renal symptoms but was effective in treating them; renal symptoms resolved in 61% of the prednisone patients after treatment, compared with 34% of the placebo patients (difference = 27%; 95% confidence interval = 3% to 47%;  $P = .024$ ). The authors concluded that the general use of prednisone in HSP is not supported, but patients with disturbing symptoms may benefit from early treatment because prednisone reduces extrarenal symptoms and is effective in altering, but not preventing, the course of renal involvement.

A long-term follow-up study published by the same authors found that patients with nephritis at the onset

of disease had an increased risk for hypertension or urinary abnormalities (OR 3.6,  $P = 0.02$ ) 8 years later. There were no differences between the placebo and prednisone groups, leading to the conclusion that early prednisone therapy does not affect long-term outcome and should not be routinely used.

In a small but well-designed study, children with HSP who displayed hypertension, hematuria, and proteinuria were given 1,000 mg fish oil twice daily and Enalapril 2.5 to 10 mg per day. Enalapril was subsequently stopped in all patients within 1 year. A 6-month follow-up was recorded under continued treatment with fish oil. Renal function remained the same (creatinine at a mean of 0.6 mg/dL) before and after treatment. Hypertension (135/82 vs 100/54;  $P < .05$ ) remained better controlled and proteinuria (1,041 mg/day vs 104 mg/day;  $P < .05$ ) remained minimal at 6-month follow-up for those off angiotensin-converting enzyme (ACE) inhibition but on fish oil. Although this case series is very small, fish oil is a benign treatment that may provide other added benefits such as the reduction of hypertriglyceridemia. Fish oils (omega-3-acid ethyl esters) have been shown to be promising in IgA nephropathy, which many researchers think is part of the spectrum of disease related to HSP. The anti-inflammatory and immune-modulating effects of fish oil have been demonstrated in other studies. ACE inhibitors are also indicated for the control of hypertension, especially for children with proteinuria.

Other options for the treatment of HSP have been studied. Cyclosporine and prednisone, plasmapheresis, tonsillectomy, dapsone, and cyclophosphamide have all been tried, with varying degrees of success. These approaches have the possibility of toxicity, and many lack verification from blinded, controlled, and randomized studies.

In summary, most children with HSP should be managed with supportive care and with close monitoring of their renal function. Children with HSP who have persistent hematuria or proteinuria or those with abnormal renal function or elevated blood pressure should be referred to nephrologists for management. There is no evidence to support the use of steroids to prevent urinary abnormalities. However, in children with significant renal involvement because of HSP nephritis, steroids and other immunosuppressants, including cyclophosphamide, may have a role in treating the disease.

### WHEN TO REFER

Children should be referred to a pediatric nephrologist if they have

- Proteinuria or hematuria
- Hypertension
- Significant and persistent signs of kidney inflammation (nephritic or nephrotic syndrome)
- Acute kidney injury (elevation in blood urea nitrogen or creatinine levels)

### WHEN TO ADMIT

- Toxic appearance (febrile, lethargic, hypotensive, or hypertensive, with altered mental status or not acting themselves)

- Abdominal pain may indicate acute appendicitis, intussusception, small-bowel obstruction or infarction or pain caused by HSP. Obtaining a surgical consult is advisable if abdominal pain is particularly severe or out of proportion to the physical examination.
- A significant reduction in urine output for age and weight or inability to keep fluids down.
- Significant gastrointestinal bleeding
- Relative indication: A significant (>25% change) alteration from normal in the child's kidney function (serum creatinine)

## Chapter 265 HEPATITIS

Winita Hardikar, MBBS, PhD; Kathleen B. Schwarz, MD

The term *hepatitis* simply describes inflammation of the liver and does not imply a cause. The causes of hepatitis vary with age, geographic location, and the presence or absence of underlying illness. Broadly speaking, hepatitis in children may be caused by infectious, autoimmune, and metabolic conditions or drug toxicity (Table 265-1). Systemic conditions such as ischemia and trauma (including abdominal battering from child abuse) may also result in elevated serum aminotransferases. Some conditions may cause elevated liver enzymes that are not because of hepatitis. These conditions include the myopathies (elevated serum aminotransferases) and bone disorders (elevated alkaline phosphatase) where the primary site of enzyme release is muscle or bone rather than the liver.

## EPIDEMIOLOGY AND CLINICAL COURSE

### Viral Hepatitis

The overall prevalence of viral hepatitis in children in the United States is declining, particularly with the implementation of routine vaccination programs for hepatitis A and B. Not included in these figures are numerous unrecognized anicteric cases, especially in children, in whom the anicteric to icteric case ratio is thought to approach 10:1. The clinical features (Table 265-2) vary from asymptomatic to fulminant hepatic failure, depending on the virus and host factors. Acute viral hepatitis may also progress to chronic liver disease, particularly with hepatitis B and C, resulting in chronic morbidity and mortality.

### Hepatitis A Virus

Hepatitis A virus (HAV) is a 27 nm ribonucleic acid (RNA) virus, a member of the picornavirus group. Transmission of HAV is predominantly by the fecal-oral route, although saliva may rarely be a vehicle. Contaminated shellfish, polluted water, and travel to endemic areas also have been identified in the acquisition of type A infection. Hepatitis A virus RNA can be detected in serum and stool as early as 2 to 3 weeks before acute illness and as much as 1 week after the onset of illness; recovery of virus in the stool decreases as jaundice becomes evident. Before symptoms develop, parenteral transmission is possible but uncommon.

Initial symptoms of HAV infection may be nonspecific and include fever, malaise, anorexia, nausea, vomiting, and upper abdominal discomfort. Darkening of the urine and enlargement and tenderness of the liver follow. Jaundice is uncommon in young children. The bilirubin level increases in both direct and indirect fractions, but, generally, does not exceed a total of 15 mg/dL. Aminotransferase elevation generally does not last more than 3 to 4 weeks. The disease rarely is fulminant; however, a small percentage of children with hepatitis A may have a relapsing or protracted course. Children with acute HAV infection may be completely asymptomatic, but are still infectious and, therefore, serve as a silent reservoir of disease.

### Hepatitis B Virus

Hepatitis B virus (HBV) is a highly infectious virus of the Hepadnaviridae family. Its double-stranded overlapping DNA codes for a surface antigen (HBsAg), a core antigen (HBcAg), e antigen (HBeAg), and DNA polymerase. Hepatitis B surface antigen is found in all body secretions and excretions from infected persons. However, transmission only occurs through contact with blood, vaginal and menstrual fluids, and semen. The virus is stable on environmental surfaces for at least 7 days. In hyperendemic areas (Asia, Africa, Southern Europe, Latin America), HBV infection is most often acquired perinatally or in early childhood by horizontal transmission from infected family members.

Improperly sterilized syringes, infected blood products, and nosocomial transmission are also means of acquisition in some parts of Africa and Asia.

Aggressive immunization programs in certain areas, such as Taiwan, have substantially lowered

**Table 265-1** Differential Diagnosis of Hepatitis

CATEGORY	CAUSES
Infectious	Hepatitis A, B, C, D, E, G, adenovirus, Epstein-Barr virus, cytomegalovirus, varicella zoster, human herpesvirus type 6, parvovirus B19, echovirus, coxsackievirus, rubeola virus
Autoimmune	Autoimmune type 1 and 2 and seronegative autoimmune hepatitis, Sclerosing cholangitis (neonatal and child forms)
Metabolic	Alpha <sub>1</sub> antitrypsin deficiency, galactosemia, hereditary tyrosinemia, hereditary fructose intolerance, progressive familial intrahepatic cholestasis types 1, 2, and 3, paroxysmal diseases, mitochondrial hepatopathies, neonatal hemochromatosis, glycogen storage disease, Niemann-Pick disease type C, inborn errors of bile acid metabolism, Wilson disease, nonalcoholic steatohepatitis
Drug induced	Sodium valproate, halothane, phenytoin, herbal medications, recreational drugs (ecstasy), toxins (eg, <i>Amanita phalloides</i> [wild mushrooms])
Other	Alagille syndrome, cystic fibrosis, ischemia, trauma (including child abuse)
Elevated liver enzymes without hepatitis	Myopathies, bone disorder, transient hyperphosphatasia, celiac disease

**Table 265-2** Clinical Features of Acute Viral Hepatitis

	HAV	HBV	HCV
<b>CHARACTERISTICS</b>			
Age distribution	Children and young adults	All age groups	All age groups
Route of infection	Predominantly fecal-oral	Parenteral	Parenteral
Incubation period (days)	15–40	50–180	20–90
Onset	Acute	Insidious	Insidious
Duration of clinical illness	Weeks	Weeks to months	Weeks to months
<b>VIRUS PRESENCE</b>			
Feces	Late incubation, acute	May be present	Absent
Blood	Late incubation, acute	Late incubation, acute, may persist for months	Present chronically
<b>SIGNS AND SYMPTOMS</b>			
Fever	High, common early	Moderate, less common	Moderate, less common
Nausea and vomiting	Common	Less common	Less common
Anorexia	Severe	Mild to moderate	Mild to moderate
Arthralgia or arthritis	Rare	Common	Absent
Rash or urticaria	Rare	Common	Absent
<b>LABORATORY FINDINGS</b>			
Aminotransferase elevation	1–3 weeks	Months	Fluctuates for months
Bilirubin elevation	Weeks	May be months	Unusual
HBsAg	Absent	Present	Absent
Severity	Usually mild	Often severe	Usually mild
Progression to chronic hepatitis	Rare	More common	High rate
Immunity	Homologous, lifelong	Homologous, lifelong	Unusual
Prevention	Immune serum globulin, vaccine	Hyperimmune globulin, vaccine	Screen donor blood

HAV, hepatitis A virus; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus.

Modified from Krugman S, Katz SL. *Infectious diseases of children*, 8th ed. St Louis, MO: Mosby; 1985; and deBelle RC, Lester R. Current concepts of acute and chronic viral hepatitis. *Pediatr Clin North Am*. 1975;22(4):943–961. Copyright © Elsevier, with permission.

both vertical and horizontal transmission rates as well as the average annual incidence of hepatocellular carcinoma.

In the United States, implementation of universal newborn hepatitis B immunization in 1991, followed in 1995 by routine vaccination of all adolescents 11 to 12 years, and, in 1999, to include children younger than

18 years of age who were not previously vaccinated resulted in a significant reduction of HBV in children. The rate of acute hepatitis B in children and adolescents decreased 89% between 1990 and 2002, and racial disparities in hepatitis B incidence narrowed. Despite these hepatitis B vaccination recommendations, a recent study showed that most homeless inner-city

children aged 13 to 18 years were not vaccinated against hepatitis B.

Age of acquisition of the virus is an important prognostic determinant. Perinatal transmission from mother to newborn leads to chronic hepatitis in 90% of affected children compared to less than 10% when the infection is acquired as an adult. Transmission and chronic infection in the newborn are more likely (up to 90%) if the mother is HBeAg positive and less likely (<5%) if the mother is HBeAg negative. Fulminant hepatitis in the newborn has been reported in the latter group and, although the mechanism is not clear, it is not thought to result from the selection of more potent mutant viruses. The principal route of infection at the time of birth is by microtransfusions or by swallowing blood and genital secretions at the time of delivery.

The clinical course of hepatitis B infection depends on several viral and host factors. Hepatitis B acquired either perinatally or horizontally at a very young age is generally asymptomatic.

In low-prevalence countries, hepatitis B occurs sporadically, and more often in adolescents. The onset is usually insidious. Extrahepatic manifestations such as skin rash and arthralgia are common and may be prodromal. In fact, hepatitis B should be kept in mind in the differential diagnosis of a serum sickness-like illness. Younger children may be asymptomatic. The duration of illness is usually 4 to 6 weeks. Aminotransferase elevation usually peaks approximately 1 month after the onset of illness.

The long-term effects of acquiring HBV in infancy include cirrhosis and hepatocellular carcinoma. Although most cases of HBV-related hepatocellular carcinoma occur in adults, many cases of HBV-related liver cancer have been described in children. Recent studies suggest that perinatal transmission is important in hepatocarcinogenesis, perhaps related to the high dose of HBV-DNA with subsequent tolerance and persistent necroinflammatory activity. In addition, the genotype of the virus may correlate with natural history, response to therapy, and risk of developing hepatocellular carcinoma.

### **Hepatitis C Virus**

Hepatitis C virus (HCV), recognized in 1989, is a single stranded RNA virus of the Flaviviridae family and was responsible for most post-transfusion non-A, non-B hepatitis prior to screening blood and blood products from 1990. The seroprevalence of HCV in the general US population is estimated at 1.8%. In children, the seroprevalence for those without known risk factors is 0.2% for those younger than 12 years of age and 0.4% for those 12 to 19 years of age. Prior to screening donor blood in 1990, most children were infected by parenteral exposure to contaminated blood and blood products. Since screening, the risk of HCV infection was substantially reduced to 0.004% to 0.0004% per unit transfused. The major cause of pediatric HCV infection is now perinatal with an overall risk of transmission of 6% from HCV antibody-positive mothers. The risk is minimal when the mother is HCV RNA negative, and higher when mothers are coinfectd with human immunodeficiency virus (HIV). A recent

European multicenter study showed no increase in transmission of HCV from HCV/HIV coinfectd mothers to their newborns. One of the explanations proposed was that effective highly active antiretroviral therapy treatment of coinfectd women leads to reduced immunosuppression and hence a reduced maternal viral load. This study also found that the risk of HCV infection doubles in female offspring, an observation that is novel and yet to be explained. Adolescents may acquire HCV through high-risk behaviors such as injection drug use, intranasal drug use, and body piercing. Horizontal transmission from parent to child, from sibling to sibling, and via sexual transmission is extremely low.

Acute HCV infection is asymptomatic in most children; however, both acute liver failure and cirrhosis have been reported in infancy. Two characteristic clinical features of HCV infection are fluctuation in the serum concentration of the aminotransferases and progression to chronicity in 50% to 90% of cases. Most infected children remain asymptomatic without stigmata of chronic liver disease. Liver histology shows mild to moderate hepatitis and fibrosis increases with duration of infection, but in an unpredictable manner. Children with chronic HCV infection who become infected with HAV are at substantial risk of fulminant hepatic failure. Chronic HCV infection predisposes to cirrhosis and hepatocellular carcinoma over 20 years in individuals with adult-acquired infection. The natural history of perinatally acquired HCV infection is still under evaluation in cohort studies.

### **Hepatitis D Virus**

Hepatitis D virus (HDV), discovered in 1977, is a defective virus that requires replication of hepatitis B virus for its own replication. The epidemiology is parallel to that for HBV infection, and prevalence has decreased significantly with better control of HBV infection. Replication occurs in the liver, and the pathologic effects of the virus are limited to this organ. The hepatitis D antigen (HDAg), can be found in both the liver and the serum of individuals who have the disease. Hepatitis D virus may occur as a coinfection with chronic HBV or as an acute superinfection of HBV; in both cases it causes a more severe illness with significant morbidity and mortality. Hepatitis D virus may also be transmitted perinatally with HBV. Acute HDV infection in a child who is a chronic HBV carrier may produce a severe episode of hepatitis with fulminant hepatic failure or chronic hepatitis.

### **Hepatitis E Virus**

Hepatitis E virus (HEV), a 27- to 34-nm single-stranded RNA virus, is the cause of epidemic, enteric transmitted hepatitis that has occurred in India, Pakistan, Nepal, Russia, China, Algeria, central Africa, Peru, and Mexico. A few imported cases have been identified in the United States and so have a few cases among persons with no history of travel to HEV-hyperendemic countries. The illness usually occurs in areas where the water supply is contaminated by feces. Hepatitis E is similar clinically to hepatitis A. Cholestasis may be more common than with hepatitis A, and elevation of serum aminotransferases is modest. The most unusual

clinical feature of the illness is its high mortality rate in pregnant women (approximately 10%).

### Hepatitis G Virus

The hepatitis G virus (HGV), identified in 1995, is an RNA virus of the Flaviviridae family and a distant relative of HCV. Hepatitis G virus is mainly transmitted parenterally through blood and blood products and through intravenous drug use. Its prevalence in children in the United States was estimated to be 13.8% based on a small study of blood bank samples. The infection may be self-limited, resulting in the production of neutralizing antibody to the E2 envelope protein, or it may result in a carrier state. The virus does not replicate in the liver and does not seem to alter the course and severity of those coinfecting with HCV, but it may be protective in HIV infection.

### TT Virus (2)

TT virus (TTV) is a DNA virus discovered in 1997 in the sera of 3 of 5 patients with biopsy-proven hepatitis and elevated serum alanine aminotransferase levels. In North America, the prevalence of TTV has been found to be 10% in volunteer blood donors, 13% of commercial blood donors, and 17% of intravenous drug users. The role of TTV in the pathogenesis of acute and chronic liver disease is yet to be determined.

### Autoimmune Hepatitis

Autoimmune hepatitis (AIH) is a chronic necroinflammatory hepatitis characterized by mononuclear cell infiltration of the portal tracts with piecemeal necrosis, hypergammaglobulinemia, and non-liver-specific auto antibodies. There are 2 types of AIH, classified according to the presence or absence of certain auto antibodies—AIH type 1 is characterized by the presence of an antinuclear antibody (ANA) and an anti-smooth-muscle antibody (ASMA), whereas AIH type 2 is characterized by anti-liver-kidney microsomal antibodies (anti-LKM). Approximately two-thirds of affected children are girls.

The mode of presentation of autoimmune hepatitis is highly variable; therefore, AIH should be excluded with serologic testing in all children presenting with signs of acute or chronic liver disease or liver failure. Hepatomegaly, splenomegaly, and jaundice are common findings. Autoimmune hepatitis is sometimes associated with inflammatory bowel disease and may precede or follow colitis. Associated extrahepatic manifestations reported include nephrotic syndrome, autoimmune thyroiditis, Behçet disease, insulin-dependent diabetes, urticaria pigmentosa, vitiligo, hypoparathyroidism, and Addison disease. Although AIH type 2 patients are more likely to present in acute liver failure, the overall prognosis of type 2 disease is not different from that of type 1 disease.

### Drug-Induced Hepatitis

Drug-induced liver disease may occur as an unexpected idiosyncratic reaction to a drug or be an expected consequence to a toxic dose and may cause signs of acute hepatitis and chronic hepatitis. Some forms of drug-induced liver disease result from the presence of polymorphisms of enzymes that metabolize

drugs, resulting in slower metabolism or the production of toxic intermediates by alternative pathways (eg, azathioprine and valproic acid-induced liver injury). The pattern and severity of injury may vary from asymptomatic abnormalities of liver function tests to acute liver failure. More than 900 drugs have been implicated as causes of liver injury.

### Metabolic Liver Disease

A large number of metabolic disorders can present as hepatitis in childhood, but a detailed discussion is beyond the scope of this chapter.

Alpha<sub>1</sub> antitrypsin ( $\alpha_1$ AT) deficiency is the most common genetic cause of liver disease in children, with an incidence of 1 in 1,600 to 2,000 live births. It results from the retention of the mutant  $\alpha_1$ AT inside the endoplasmic reticulum of liver cells, which may predispose certain individuals with homozygous ZZ phenotype to significant liver injury.

Wilson disease is an autosomal-recessive disorder affecting 1 in 30,000 people, resulting from a mutation in the *ATP7B* gene, which encodes a copper-binding membrane protein regulating the transport of copper across cell membranes. More than 200 mutations that may produce disease in humans have been identified. Accumulation of copper in the hepatocytes and other organs results in a constellation of clinical symptoms, including hepatitis, neuropsychiatric disease, and Kayser-Fleischer (KF) rings in the Descemet membrane of the cornea.

Tyrosinemia (hereditary tyrosinemia type 1) is an autosomal-recessive disease resulting from a deficiency in fumarylacetoacetate hydrolase, the last enzyme in the tyrosine degradation pathway. This deficiency leads to an accumulation of intermediary toxic metabolites such as maleyl- and fumaryl-acetoacetate, which are thought to cause hepatorenal damage and eventually hepatocellular carcinoma. The usual presentation in infants is acute liver failure with pronounced coagulopathy.

Galactosemia is an autosomal-recessive disorder caused by a deficiency of galactose 1 phosphate uridyl transferase. It presents in the neonatal period with cholestatic jaundice, hypoglycemia, encephalopathy, vomiting, failure to thrive, and hepatitis. Hereditary fructose intolerance (HFI) is a rare condition with an estimated prevalence of 1 in 20,000 individuals. The absence of the enzyme aldolase B results in the buildup of fructose-1-phosphate, which inhibits gluconeogenesis and glycolysis. The infant with ongoing fructose ingestion presents with metabolic acidosis, hypoglycemia, and liver failure.

Progressive familial intrahepatic cholestasis (PFIC) type 1, or Byler disease, results from a mutation in the *FIC1* gene, which codes for a P-type adenosine triphosphatase involved in aminophospholipid transport. The mechanism by which cholestatic injury occurs in this condition is still to be determined. Progressive familial intrahepatic cholestasis type 2 is caused by a mutation in the gene encoding for the main adenosine triphosphate-dependent bile acid pump on the canalicular membrane (BSEP). Progressive familial intrahepatic cholestasis type 3 results from a mutation in the gene encoding the multiple

drug resistance protein, which is a phospholipid flippase also located on the canalicular membrane. Progressive familial intrahepatic cholestasis types 1 and 2 present with cholestatic liver disease in infancy. The presentation of PFIC type 3 is variable in childhood. In infants it may present with clinical features of biliary obstruction, but a normal biliary tree on imaging, while older children may present with gallstones. Inborn errors of bile acid metabolism are also rare, but present with severe cholestatic liver disease necessitating early recognition and treatment as outlined in the following text.

Alagille syndrome, or paucity of the intrahepatic bile ducts, is caused by a mutation in the human *jagged 1* gene. Approximately 50% of patients inherit the disease in an autosomal-dominant fashion, while the other 50% of cases result from spontaneous mutations in the index case (proband). Although multiple mutations have been identified, genotype-phenotype correlations are a little more difficult, and the pathophysiology of the gene mutation is yet to be elucidated. More recently, mutations in the gene encoding the notch receptor were also found in patients with the clinical features of Alagille syndrome. Diagnosis in the proband still relies largely on clinical criteria and is based on the association of bile duct paucity together with at least 3 of the following: typical facies, posterior embryotoxon (ophthalmological examination), butterfly vertebrae (seen on chest radiograph), consistent cardiac disease (eg, pulmonary stenosis), and renal disease. Other features include a markedly elevated gamma-glutamyl transferase (GGT), hypercholesterolemia, growth retardation, and intracranial bleeding. Genetic testing available in selected centers may be useful in family studies, as the penetrance is variable.

### Evaluation

A careful clinical history and examination are important in making a timely diagnosis and avoiding the need for unnecessary investigations. Referral to a pediatric gastroenterologist is recommended, as many of the conditions are uncommon and require close monitoring. The evaluation of a child with hepatitis depends primarily on the child's age and the nature of the presentation. Common presentations include jaundice in infancy or childhood, the incidental finding of elevated liver enzymes during routine workup, or fulminant hepatic failure. Assessment of children in each of these categories is described in the following text.

**NEONATAL JAUNDICE.** The infant with jaundice and elevated liver enzymes may be otherwise well or have failure to thrive or even display signs of liver decompensation. It is important to determine if there is a family history of jaundice, liver or metabolic disease, or maternal exposure to drugs or toxins, as well as maternal serological status for hepatitis A, B, and C. Maternal illnesses during pregnancy should also be noted, particularly in an infant who is malnourished, suggesting the presence of an in utero infection. A careful dietary history to determine fructose ingestion in the infant either through feed or medication is required if HFI is suspected. The association of renal Fanconi syndrome and clotting abnormalities unresponsive to vitamin K therapy should suggest

tyrosinemia. Gestational alloimmune liver disease (formerly called "neonatal hemochromatosis") may also present with hepatitis but often presents with acute liver failure in newborns. Examination of the infant may reveal hepatosplenomegaly, icterus, and little else. Dysmorphic features and cardiac murmurs would be suggestive of Alagille syndrome.

Basic liver function tests will suggest whether the underlying condition is predominantly hepatocellular injury (elevated transaminases) or predominantly obstructive (elevated GGT and alkaline phosphatase), although in infants the pattern is often mixed. Investigations in the infant in whom an etiology is not obvious should include serology for viruses as well as general investigations such as a blood ammonia level, serum glucose, blood gases with pH, blood lactate level, urine metabolic screen and reducing substances, red blood cell galactose-1-phosphate uridyl transferase, thyroid function tests, and serum and urine bile acids. Other conditions that should be considered in an infant with jaundice include  $\alpha_1$  AT deficiency, cystic fibrosis, defects in amino acid synthesis, organic acid synthesis and fatty acid oxidation, glycogen storage disease, and Niemann Pick type C. More sophisticated tests are required for many metabolic and inherited disorders (see Table 265-3).

**THE CHILD WITH JAUNDICE.** Viral hepatitis, particularly HAV, HBV, HCV, and Epstein-Barr virus should be actively sought in this age group. Hepatitis A is diagnosed by the presence of immunoglobulin M class anti-hepatitis A, which is present 5 to 10 days after exposure. Hepatitis A virus immunoglobulin (IgG) is present at least 10 years after infection and probably confers lifelong immunity to the virus.

The presence of HBsAg in the serum implies hepatitis B infection (see Table 265-4). This is the first marker to appear and is detected 2 weeks to 6 months postexposure. Children with HBV infection are initially HBsAg and HBeAg positive. Hepatitis B virus e antigen reflects active viral replication and infectivity. During this immunotolerant stage, which may persist for years, viral replication and serum HBV-DNA levels are very high. The child is very infectious and may occasionally serve as a source of horizontal transmission in the community. Serum aminotransferase levels fluctuate and may be in the upper limit of normal range. During childhood, conversion from HBeAg to anti-hepatitis B e antigen (HBe) may occur spontaneously with a rate of 3% per year, although rates vary with the mode of acquisition. Seroconversion to anti-HBe is often preceded by a transient elevation in serum aminotransferases. After anti-HBe seroconversion, HBV-DNA levels remain low or undetectable. In this state, children may once again develop fluctuations of alanine aminotransferase and a rise in DNA levels, indicating increased replication of a precore mutant virus that does not produce e antigen.

Most children remain HBsAg positive, and this chronic carrier state is generally unassociated with overt disease during childhood. The annual HBsAg clearance rate is low (1%–2%) and may be associated with persistence of HBV-DNA. Liver cirrhosis is encountered in 3% to 5% of children with chronic HBV. These children are at risk for developing hepatocellular

**Table 265-3** Diagnostic Investigations for Liver Diseases

DISEASE	INVESTIGATION	INTERPRETATION
$\alpha_1$ AT deficiency	Serologic Pi type	MM (normal) ZZ ( $\alpha_1$ AT deficiency)
	Serum $\alpha_1$ AT	<50 mg/dL
	Liver biopsy	PAS-positive diastase-resistant granules in the hepatocyte endoplasmic reticulum
Tyrosinemia	Urinary succinyl acetone	Elevated
	$\alpha$ -fetoprotein	Raised (indicative of immature hepatocytes) May be raised in many types of neonatal hepatitis, but significantly raised in tyrosinemia
PFIC 1, 2, 3	Serum bile acids	Raised
PFIC 1, 2	GGT	Low
PFIC 3	GGT	High
Bile acid metabolic disorder	Fast atom bombardment mass spectroscopy of urine	Typical profiles
	Serum bile acids	Low
	GGT	Low
HFI	Urine-reducing substances	Positive when ingesting fructose
	Gene testing	22 mutations for HFI; 70% of patients have 2 mutations in exon 5 ( <i>A149P</i> , <i>A174D</i> )
Cystic fibrosis	Sweat chloride test	Sweat chloride >60 mEq/L
Autoimmune hepatitis		ANA; anti-SMA or anti-LKM
Neonatal hemochromatosis	Serum transferrin	Low (reflects low-functioning liver cell mass)
	Serum ferritin	Markedly raised (nonspecific)
	MRI	Siderosis of pancreas, myocardium
	Buccal biopsy	Siderosis of salivary glands
Niemann-Pick type C	Liver biopsy (electron microscopy)	Whirled inclusions of sphingomyelin in lysosomes
	Skin fibroblast culture	Measurement of sphingomyelinase activity

$\alpha_1$  AT,  $\alpha_1$ -antitrypsin; ANA, antinuclear antibody; *anti-LKM*, anti-liver-kidney microsomal antibodies; *anti-SMA*, anti-smooth-muscle antibody; GGT,  $\alpha$ -glutamyltransferase; HFI, hereditary fructose intolerance; MRI, magnetic resonance imaging; PAS, periodic acid-Schiff; PFIC, progressive familial intrahepatic cholestasis; SMA, smooth-muscle antibody.

**Table 265-4** Diagnostic Tests for Hepatitis B Virus (HBV) Antigens and Antibodies

FACTOR TO BE TESTED	HBV ANTIGEN OR ANTIBODY	USE
HBsAg	Hepatitis B surface antigen	Detection of acutely or chronically infected people; antigen used in hepatitis B vaccine; can be detected for up to a month after a dose of hepatitis B vaccine
Anti-HBs	Antibody to HBsAg	Identification of people who have resolved infections with HBV; determination of immunity after immunization
HBeAg	Hepatitis B e antigen	Identification of infected people at increased risk of transmitting HBV
Anti-HBe	Antibody to HBeAg	Identification of infected people with lower risk of transmitting HBV
Anti-HBc (total)	Antibody to HBcAg <sup>a</sup>	Identification of people with acute, resolved, or chronic HBV infection (not present after immunization); passively transferred maternal anti-HBc is detectable for as long as 24 months among infants born to HBsAg-positive women
IgM anti-HBc	IgM antibody to HBcAg	Identification of people with acute or recent HBV infections (including HBsAg-negative people during the "window" phase of infection; unreliable for detecting perinatal HBV infection)

HBcAg, hepatitis B core antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; IgM, immunoglobulin M.

<sup>a</sup>No test is available commercially to measure HBcAg.

From American Academy of Pediatrics. Hepatitis B. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee of Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:400–423.

carcinoma before adulthood. Although the best methods and frequency of surveillance have not been determined, careful follow-up, including serial serum  $\alpha$ -fetoprotein measurements and liver ultrasound examinations, should be performed on these children.

Hepatitis B virus DNA is detectable in serum very early in the infection. Hepatitis B virus DNA levels are now reported as international units per milliliter (IU/mL). The levels of HBV-DNA may vary considerably, and several assays with different dynamic ranges

are used. The most sensitive real-time polymerase chain reaction (PCR) assays can detect as little as 20 IU/mL; the branched chain DNA assays are less sensitive. The measurement of HBV-DNA levels is important in light of recent data suggesting that long-term outcome from HBV infection, particularly the development of hepatocellular carcinoma, is directly related to the degree of viral suppression resulting from therapy. Anti-hepatitis B surface antibody indicates immune response to immunization or past infection. The presence of anti-hepatitis B core antibody (HBc), which appears 3 to 5 weeks after HBsAg, implies exposure to the native virus. Anti-HBc does not appear after vaccination.

The presence of antibodies to HCV implies exposure to HCV virus, but does not confer protective immunity. Most laboratories currently use third-generation enzyme-linked immunosorbent assay which has over 99% sensitivity and specificity. However, these tests become positive weeks after exposure to the virus. In contrast, the highly sensitive PCR assay becomes positive within days after exposure to the virus. Assays for viral detection may be quantitative or qualitative. The latter are more sensitive; however, as quantitation is an important component of guiding therapy, quantitative assays are used more often. As with HBV infection, the international unit has been adopted as a means of overcoming the variability between laboratories and different commercially available assays. Vertically acquired infection is confirmed by the persistence of anti-HCV antibody beyond 18 months of age or the presence of HCV-RNA in serum after the first 3 months of life. Polymerase chain reaction (PCR) testing prior to this period is unreliable.

A test for anti-HDV is commercially available. Serologic identification of anti Hepatitis E Virus IgM (anti HEV IgM) is diagnostic, and real-time PCR was recently developed. Hepatitis G virus and TTV infections are diagnosed by detection of HGV-RNA and TTV-DNA by PCR methods.

Diagnosis of autoimmune hepatitis relies on a combination of hypergammaglobulinemia and raised anti-nuclear, smooth-muscle, or liver-kidney microsomal antibodies. Histologically, portal tracts are infiltrated by lymphocytes and plasma cells. Inflammatory cells often infiltrate the parenchyma, accompanied by necrosis of cells at the periphery of the hepatic lobule (piecemeal necrosis). Fibrosis may be seen to a variable degree, or true cirrhosis may be present. In 1999, the International Autoimmune Hepatitis group modified a scoring system to diagnose AIH in adults. This was evaluated by Schreiber and colleagues in 2004 and was found to be useful in children, particularly when the ratio of GGT:AST (aspartate aminotransferase) was used instead of the ratio of alkaline phosphatase:AST. The GGT to AST ratio is better at detecting autoimmune disease with a biliary component, such as overlap syndrome.

Metabolic diseases that present later in childhood include Wilson disease,  $\alpha_1$  AT deficiency, and fatty liver. Wilson disease should always be considered in the differential diagnosis of pediatric liver disease, as it has a variable presentation and effective therapy is available. There is no single test available to

diagnose Wilson disease. The combination of 2 or more of the following is highly suggestive: decreased serum ceruloplasmin ( $<20$  mg/dL), elevated urinary copper excretion ( $>100$  mcg/24 hours), elevated liver copper concentration ( $>250$  mcg/g of dry weight) and KF rings. Genetic confirmation is available in some centers.

Nonalcoholic steatohepatitis (NASH) is fat in the liver associated with inflammation. It has a slight male predominance and generally presents in the prepubertal age group. Nonalcoholic steatohepatitis is seen in children with a number of risk factors including obesity (body mass index  $>30$ ), diabetes, insulin resistance, and hypertriglyceridemia. Acanthosis nigricans is a marker of insulin resistance and should be looked for. While many children are obese, only a minority have NASH; hence, other mechanisms are clearly involved. A fatty liver can be identified on sonography by the presence of uniform or patchy increased echogenicity. Liver biopsy, although not necessary, shows steatosis, mixed lobular inflammation, and hepatocyte ballooning. Hereditary fructose intolerance can also present in the older child with an aversion to fructose-containing products who develops vomiting and elevation of serum aminotransferases after inadvertent ingestion.

To evaluate for drug- or toxin-induced hepatitis, a thorough medical history should be obtained for prescribed medications, herbal teas, poisons, and ingestion of wild mushrooms. Acetaminophen toxicity is the most common cause for acute liver failure in children in North America, so a serum acetaminophen level should be drawn on presentation and appropriate therapy instituted immediately as outlined in the following text. A urine toxicology screen should also be performed when the index of suspicion is high.

Liver biopsy is required when chronic liver disease is suspected and cannot be diagnosed with the investigations described earlier, and to determine the degree of inflammation and fibrosis, both of which may influence treatment. A needle biopsy is usually adequate, and the risks are low when clotting function is normal, ultrasound guidance is used, and the biopsy is performed by an experienced physician. The biopsy should be sent for histology with additional stains (eg, copper, iron), if necessary. If a metabolic liver disease is suspected, a small sample should be preserved in glutaraldehyde for electron microscopy. If Wilson disease is suspected, hepatic copper should be quantified; it is usually necessary to obtain a second biopsy core for this purpose.

**INCIDENTAL FINDINGS OF ABNORMAL LIVER ENZYMES.** Many liver diseases can present in a “silent” fashion in children, with abnormal liver enzymes being detected incidentally. These include viral hepatitis, metabolic disorders such as Wilson disease,  $\alpha_1$  AT deficiency, NASH, autoimmune hepatitis, and hemochromatosis. Conversely, systemic disorders may produce aminotransferases as outlined in Table 265-2. Raised aminotransferases have been found in 32% of children with celiac disease, and a celiac screen should be performed in all children with unexplained elevation of serum aminotransferases once hepatological causes are excluded. Similarly, evidence of muscle disorders (serum creatine kinase) and red cell

**Table 265-5** Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines<sup>a</sup>

AGE (YR)	VACCINE	HEPATITIS A ANTIGEN DOSE	VOLUME PER DOSE (ML)	NUMBER OF DOSES	SCHEDULE
12 mo–18 y	Havrix	720 ELU	0.5	2	Initial and 6–12 mo later
12 mo–18 y	Vaqtat	25 U <sup>b</sup>	0.5	2	Initial and 6–18 mo later
19 y or older	Havrix	1440 ELU	1.0	2	Initial and 6–12 mo later
19 y or older	Vaqtat	50 U <sup>b</sup>	1.0	2	Initial and 6–18 mo later
18 y or older	Twinrix <sup>c</sup>	720 ELU	1.0	3 or 4	Initial, 1 mo, and 6 mo later OR Initial, 7 days, and 21–30 days, followed by a dose at 12 mo

ELU, Enzyme-linked immunosorbent assay units.

<sup>a</sup>Havrix and Twinrix are manufactured by Glaxo Smith Kline Biologicals (Research Triangle Park, NC); Vaqtat is manufactured and distributed by Merck & Co, Inc. (Whitehouse Station, NJ).

<sup>b</sup>Antigen units (each unit is equivalent to approximately 1 mcg of viral protein).

<sup>c</sup>A combination of hepatitis B (Engerix-B, 20 µg) and hepatitis A (Havrix, 720 ELU) vaccine (Twinrix) is licensed for use in people 18 years and older in 3- and 4-dose schedules.

From American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:391–399.

disorders (complete blood count and peripheral smear, reticulocyte count, and haptoglobin levels) should be performed if there is no clinical evidence of liver disease.

**FULMINANT HEPATIC FAILURE.** The broad definition of fulminant hepatic failure (ie, hepatic encephalopathy within 8 weeks of onset of illness) is problematic in children because of the difficulty in detecting encephalopathy in infants and young children and the fact that encephalopathy may present late or not at all. The important components of the definition are the lack of a pre-existing liver disease and severe impairment of hepatic function as evidenced by a prolonged prothrombin time (>4 seconds over control) and an international normalized ratio (INR) greater than 1.5, unresponsive to large doses of vitamin K.

The cause of fulminant hepatic failure is age-dependent, but acetaminophen toxicity is the most common identified cause in the United States from the recent acute liver failure study group data. In infancy, metabolic disorders such as galactosemia, hereditary fructose intolerance, tyrosinemia, and gestational allo-immune liver disease may present with fulminant failure; therefore, appropriate investigations should be sent for these disorders (Table 265-3). In the older child, Wilson disease, autoimmune hepatitis (particularly type 2), and medications and toxins should be sought.

## THERAPY AND PREVENTION

### Viral Hepatitis

There are 2 inactivated vaccines against HAV currently approved in the United States for children 1 to 18 years old and for adults. The vaccine is given in a 2- or 3-dose schedule depending on the formulation. Table 265-5 shows the recommended doses for HAV vaccination. In the past, only children with underlying liver disease were recommended to receive HAV vaccination. However, the vaccine is now recommended for all children 1 to 18 years of age (Box 265-1). A combination of Hepatitis A and Hepatitis B vaccine is also available for individuals over 18 years old.

### BOX 265-1 Indications for Hepatitis A Virus Vaccination

- All children in the United States 12–23 months of age
- Catch-up immunization of unimmunized children 2–18 years of age, especially in the context of rising incidences or ongoing outbreaks among children and adolescents
- Travelers to endemic areas
- Close contacts of newly arrived international adoptees
- Patients with chronic liver disease
- Patients with clotting factor disorders
- Men who have sex with men
- Users of injection and illicit drugs
- Patients at high risk of exposure secondary to their occupation

Derived from American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:391–399.

Recommendations for pre-exposure immunoprophylaxis of HAV for subjects of all ages are shown in Table 265-6. Either pediatric formulation induces seroconversion rates greater than 90% after the initial dose and 100% after the second dose.

Hospitalization generally is unnecessary for the child who has acute viral hepatitis; however, the infant and young child should be hospitalized if there is coagulopathy or other evidence of liver decompensation. No particular diet or restriction of activity seems to affect the course or outcome of acute viral hepatitis, because recovery of HAV in the child's stool decreases rapidly after the onset of jaundice. Return to school at this point, provided the child feels well, does not seem to present an undue risk of infection to others. Although household contacts of the child with hepatitis

**Table 265-6** Recommendations for Preexposure Immunoprophylaxis of Hepatitis A Virus for Travelers<sup>a</sup>

AGE	RECOMMENDED PROPHYLAXIS	NOTES
<12 mo	IGIM	0.02 mL/kg <sup>b</sup> protects for up to 3 mo. For trips $\geq 3$ mo, 0.06 mL/kg <sup>b</sup> should be given at departure and every 5 mo if exposure to HAV continues.
12 mo–40 y $\geq 41$ y	HepA vaccine <sup>c</sup> HepA vaccine, with or without IGIM <sup>c</sup>	If departure is in <2 wk, older adults, immunocompromised people, and people with chronic liver disease or other chronic medical conditions can receive IGIM with the initial dose of HepA vaccine to ensure optimal protection.

IGIM, immune globulin intramuscular; HepA, hepatitis A vaccine.

<sup>a</sup>All people 12 months or older at high risk of HAV disease should be immunized routinely.

<sup>b</sup>IGIM should be administered deep into a large muscle mass. Ordinarily, no more than 5 mL should be administered in one site in an adult or large child; lesser amounts (maximum 3 mL in one site) should be given to small children and infants.

<sup>c</sup>People who have a contraindication to HepA vaccine should receive IGIM.

From American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:391–399.

**Table 265-7** Recommendations for Postexposure Immunoprophylaxis of Hepatitis A

TIME SINCE EXPOSURE	AGE OF PATIENT (YR)	RECOMMENDED PROPHYLAXIS
$\leq 2$ wk	<12 mo	IGIM, 0.02 mL/kg <sup>a</sup>
	12 mo–40 y	HepA vaccine <sup>b</sup>
	$\geq 41$ yr	IGIM, 0.02 mL/kg, <sup>a</sup> but HepA vaccine <sup>b</sup> can be used if IGIM is unavailable <sup>a</sup>
>2 wk	People of any age who are immunocompromised, have chronic liver disease, or contraindication to vaccination	IGIM, 0.02 mL/kg <sup>a</sup>
	<12 mo	No prophylaxis
	$\geq 12$ mo	No prophylaxis, but HepA vaccine may be indicated for ongoing exposure <sup>b</sup>

IGIM, Immune globulin intramuscular; HepA, hepatitis A vaccine.

<sup>a</sup>IGIM should be administered deep into a large muscle mass. Ordinarily, no more than 5 mL should be administered in one site in an adult or large child; lesser amounts (maximum 3 mL in one site) should be given to small children and infants.

<sup>b</sup>Dose and schedule of hepatitis A vaccine as recommended according to age in Table 265-5.

From American Academy of Pediatrics. Hepatitis A. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:391–399.

A are already likely to be infected by the time of diagnosis, infection control measures should be instituted, including scrupulous handwashing and the use of disposable eating utensils in the child's home until jaundice clears. Pooled serum Ig, when given within 2 weeks postexposure, is effective in preventing symptomatic infection, as is immunization within an 8-day window period. Immunoprophylaxis should be given to household, sexual, child care center, and hospital contacts, and may be recommended in some situations for schoolroom contacts and persons exposed in common source outbreaks (Table 265-7). Newborns of infected mothers do not need special care if the mother is not jaundiced. Children traveling to endemic areas should also be immunized prophylactically. Vaccination is preferable; however, if travel is imminent (ie, <1 month), IgG may be substituted per Centers for Disease Control and Prevention guidelines.

A significant reduction in the prevalence of Hepatitis B has been accomplished to some extent with infant and catch-up vaccination programs over the last 2

decades. Detailed recommendations regarding doses and pre-exposure and postexposure prophylaxis are provided in Box 265-2, Table 265-8, Table 265-9, and Table 265-10. A baby born to an HBsAg-positive mother, or a mother who had hepatitis B during pregnancy, should be given 0.5 mL of hepatitis B immune globulin (HBIG) intramuscularly within the first 12 hours of life and 0.5 mL of hepatitis B vaccine intramuscularly at a different site before hospital discharge, but definitely within the first week of life and again at 1 and 6 months of age. Data linking breastfeeding to the acquisition of viremia are equivocal, but HBsAg-positive mothers whose infants received immunoprophylaxis may breast feed without risk of transmitting HBV to the infant. Hepatitis B immunization also protects against HDV infection.

The decision to treat a child with HBV is complex and should be made in conjunction with a pediatric hepatologist. The 2 major classes of medication available are the interferons and nucleoside/tide analogs. Treatment does not usually eradicate the virus, but can

**BOX 265-2 Persons Who Should Receive Hepatitis B Immunization**

- All infants (infants of HBsAg-positive mothers require postexposure immunoprophylaxis with HBIG and vaccine)
- All children and adolescents not vaccinated as infants
- Inmates of juvenile detention correctional facilities
- **People at Risk of Infection by Sexual Exposure**
  - Sex partners of HBsAg-positive people
  - Sexually active people who are not in a long-term mutually monogamous relationship (eg, people with >1 sex partner during the previous 6 months)
  - People seeking evaluation or treatment for a sexually transmitted infection
  - Men who have sex with men
- **People at Risk of Infection by Percutaneous or Mucosal Exposure to Blood**
  - Current or recent injection drug users
  - Household contacts of HBsAg-positive people
- Residents and staff of facilities for people with developmental disabilities
- Health care and public safety workers with reasonably anticipated risk of exposure to blood or blood-contaminated body fluids
- People with end-stage renal disease, including predialysis, hemodialysis, peritoneal dialysis, and home dialysis
- People with diabetes mellitus who are >19 years of age
- **Others**
  - International travelers to regions with high or intermediate levels (HBsAg prevalence of  $\geq 2\%$ ) of endemic HBV infection
  - People with chronic liver disease
  - People with HIV infection
  - All other people seeking protection from HBV infection

HBIG, hepatitis B immunoglobulin; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HIV, human immunodeficiency virus. Modified from Centers for Disease Control and Prevention. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP). Part II: immunization of adults. *MMWR Recomm Rep*. 2006;55(RR-16):1–33

**Table 265-8**      **Guide to Postexposure Immunoprophylaxis of Unimmunized People to Prevent Hepatitis B Virus (HBV) Infection**

TYPES OF EXPOSURE	IMMUNOPROPHYLAXIS <sup>a</sup>
Household contact of HBsAg-positive person	Administer hepatitis B vaccine series
Discrete exposure to an HBsAg-positive source <sup>b</sup> :	
• Percutaneous (eg, bite, needlestick, nonintact skin) or mucosal exposure to HBsAg-positive blood or body fluids	Administer hepatitis B vaccine + HBIG; complete vaccine series
• Sexual contact or needle sharing with an HBsAg-positive person	Administer hepatitis B vaccine + HBIG; complete vaccine series
• Victim of sexual assault/abuse by a perpetrator who is HBsAg positive	Administer hepatitis B vaccine + HBIG; complete vaccine series
Discrete exposure to a source with unknown HBsAg status:	
• Percutaneous (eg, bite, needlestick) or mucosal exposure to blood or body fluids with unknown HBsAg status	Administer hepatitis B vaccine series
• Victim of sexual assault/abuse by a perpetrator with unknown HBsAg status	Administer hepatitis B vaccine series
Susceptible child biting someone with chronic HBV infection	Initiate or complete the hepatitis B vaccine series Do not give HBIG (assumes no oral mucosal disease when the amount of blood transferred from a child with chronic HBV infection is small)

HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

<sup>a</sup>Immunoprophylaxis should be administered as soon as possible, preferably within 24 hours after exposure. Studies are limited on the maximum interval after exposure during which postexposure prophylaxis is effective, but the interval is unlikely to exceed 7 days for percutaneous exposures and 14 days for sexual exposures.

<sup>b</sup>If person previously was immunized with hepatitis B vaccine series, administer hepatitis B vaccine booster dose.

From American Academy of Pediatrics. Hepatitis B. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:400–423.

result in seroconversion, suppression of the viral load, and a reduction in inflammation. Treatment is generally offered to children who have prolonged significantly abnormal liver function tests and who fail to seroconvert spontaneously or those with evidence of hepatocellular injury on biopsy. Regardless of

treatment, all children with HBV should be monitored for signs of evolving chronic liver disease, including clinical examination, liver function tests, alpha fetoprotein, and viral markers as outlined earlier. Recommendations for both monitoring and treating HBV in children were recently published.

Table 265-9 Recommended Dosages of Hepatitis B Vaccines

PATIENTS	VACCINE <sup>a</sup>		COMBINATION VACCINES		
	RECOMBIVAX HB <sup>b</sup> DOSE, $\mu$ G (mL)	ENGRIX-B <sup>c</sup> DOSE, $\mu$ G (mL)	COMVAX <sup>d</sup> DOSE, $\mu$ G (mL)	PEDIARIX <sup>e</sup> DOSE, $\mu$ G (mL)	TWINRIX <sup>f</sup> DOSE, $\mu$ G (mL)
Infants of HBsAg-negative mothers and children and adolescents <20 y	5 (0.5)	10 (0.5)	5 $\mu$ g HBsAg (0.5)	10 $\mu$ g HBsAg (0.5)	Not applicable
Infants of HBsAg-positive mothers (HBIG [0.5 mL] also is recommended)	5 (0.5)	10 (0.5)	5 $\mu$ g HBsAg (0.5)	10 $\mu$ g HBsAg (0.5)	Not applicable
Adolescents 11–15 y of age <sup>b</sup>	10 (1)	Not applicable	Not applicable	Not applicable	Not applicable
Adults $\geq$ 20 y	10 (1)	20 (1)	Not applicable	Not applicable	20 (1)
Adults undergoing dialysis and other immunosuppressed adults	40 (1) <sup>g</sup>	40 (2) <sup>h</sup>	Not applicable	Not applicable	Not applicable

HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin.

<sup>a</sup>Both vaccines are administered in a 3-dose schedule at 0, 1, and 6 months; 4 doses may be administered if a birth dose is given and a combination vaccine is used (at 2, 4, and 6 months) to complete the series. Only single-antigen hepatitis B vaccine can be used for the birth dose. Single-antigen or combination vaccine containing hepatitis B vaccine may be used to complete the series.

<sup>b</sup>Available from Merck & Co Inc. (Whitehouse Station, NJ). A 2-dose schedule, administered at 0 months and then 4 to 6 months later, is licensed for adolescents 11 through 15 years of age using the adult formulation of Recombivax HB (10  $\mu$ g [Merck & Co Inc.]).

<sup>c</sup>Available from GlaxoSmithKline Biologicals (Research Triangle Park, NC). The US Food and Drug Administration also has licensed this vaccine for use in an optional 4-dose schedule at 0, 1, 2, and 12 months for all age groups. A 0-, 12-, and 24-months schedule is licensed for children 5 through 16 years of age for whom an extended administration schedule is appropriate based on risk of exposure.

<sup>d</sup>Available from Merck & Co Inc. A combination of hepatitis B (Recombivax, 5  $\mu$ g) and *Haemophilus influenzae* type b (PRP-OMP) vaccine is approved for use at 2, 4, and 12 through 15 months of age (Comvax). This vaccine should not be administered at birth, before 6 weeks of age, or after 71 months of age.

<sup>e</sup>A combination of diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated poliovirus (IPV), and hepatitis B (Engerix-B 10  $\mu$ g) is approved for use at 2, 4, and 6 months of age (Pediarix [GlaxoSmithKline]). This vaccine should not be administered at birth, before 6 weeks of age, or at 7 years of age or older.

<sup>f</sup>A combination of hepatitis B (Engerix-B, 20  $\mu$ g) and hepatitis A (Havrix, 720 enzyme-linked immunosorbent assay units [ELU]) vaccine; Twinrix is licensed for use in people 18 years of age and older in a 3-dose schedule at 0, 1, and 6 months. Alternately, a 4-dose schedule at days 0, 7, and 21 to 30 followed by a booster dose at 12 months may be used.

<sup>g</sup>Special formulation for adult dialysis patients given at 0, 1, and 6 months.

<sup>h</sup>Two 1-mL doses given in 1 or 2 injections in a 4-dose schedule at 0, 1, 2, and 6 months of age.

From American Academy of Pediatrics. Hepatitis B. In: *Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:400–423.

**Table 265-10** Recommendations for Hepatitis B Virus (HBV) Prophylaxis After Occupational Percutaneous or Mucosal Exposure to Blood or Body Fluids<sup>a</sup>

EXPOSED PERSON	TREATMENT WHEN SOURCE IS		
	HBsAg POSITIVE	HBsAg NEGATIVE	UNKNOWN OR NOT TESTED
Unimmunized	Administer HBIG <sup>b</sup> (1 dose) and initiate HBV series	Initiate HBV series	Initiate HBV vaccine series
Previously immunized			
Known responder	No treatment	No treatment	No treatment
Known nonresponder		No treatment	If known high-risk source, treat as if source were HBsAg positive
After 3 doses:	HBIG: 1 dose and initiate reimmunization <sup>c</sup>		
After 6 doses:	HBIG: 2 doses separated by 1 month		
Response unknown	Test exposed person for anti-HBs <sup>d</sup>	No treatment	Test exposed person for anti-HBs <sup>d</sup>
	If adequate, no treatment		• If adequate, no treatment
	If inadequate, HBIG × 1 and vaccine booster		• If inadequate, vaccine booster dose <sup>e</sup>

HBsAg, hepatitis B surface antigen; HBIG, hepatitis B immune globulin; anti-HBs, antibody to HBsAg.

<sup>a</sup>Centers for Disease Control and Prevention. Immunization of health-care personnel: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR Recomm Rep*. 2011;60(RR-7):1–45

<sup>b</sup>Dose of HBIG, 0.06 mL/kg, intramuscularly.

<sup>c</sup>The option of giving 1 dose of HBIG (0.06 mL/kg) and reinitiating the vaccine series is preferred for nonresponders who have not completed a second 3-dose vaccine series. For people who previously completed a second vaccine series but failed to respond, 2 doses of HBIG (0.06 mL/kg) are preferred, 1 dose as soon as possible after exposure and the second 1 month later.

<sup>d</sup>Adequate anti-HBs is  $\geq 10$  mIU/mL.

<sup>e</sup>The person should be evaluated for antibody response after the vaccine booster dose. For people who receive HBIG, anti-HBs testing should be performed when passively acquired antibody from HBIG no longer is detectable (eg, 4–6 months); for people who did not receive HBIG, anti-HBs testing should be performed 1 to 2 months after the vaccine booster dose. If anti-HBs is inadequate (less than 10 mIU/mL) after the vaccine booster dose, 2 additional doses should be administered to complete a 3-dose reimmunization series, followed by postimmunization testing for anti-HBs and HBsAg.

From American Academy of Pediatrics. Hepatitis B. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:400–423.

Currently, no vaccine is available for the prevention of HCV infection. Natural infection does not protect from reinfection with the same or different genotypes either in patients or experimentally infected chimpanzees. The most important strategies for controlling hepatitis C include screening donor blood for anti-HCV, identifying and educating those at risk, and risk minimization programs for intravenous drug users. Recommendations for screening include injection drug users, hemodialysis patients, recipients of 1 or more units of blood or blood products before 1992, children with clinical non-A hepatitis, non-B hepatitis, infants born to mothers infected with HCV after 12 months of age, and international adoptees born to high-risk mothers.

Perinatal transmission of HCV is now the most common route of infection in children, with rates on the order of 4% to 6% of births to HCV-infected mothers. Maternal-fetal transmission has also been linked to in utero monitoring and prolonged rupture of membranes; it does not seem to be prevented by cesarean section.

Although HCV RNA has been detected in breast milk, current evidence suggests that breastfeeding is not contraindicated. However, mothers should consider abstaining from breastfeeding if their nipples are cracked and bleeding. Patients with HCV infection should be counseled to avoid hepatotoxic medications and alcohol and should receive vaccination against

HAV and HBV infections to prevent additional liver damage.

Treatment regimens for HCV have advanced considerably over the last 5 to 10 years with the development of individualized treatment algorithms based on genotype of the virus and response rates at various times during therapy. More recently, the development of a genetic marker for interferon sensitivity (IL28B), as well a marker for the risk of hemolysis with ribavirin, allowed further refining of individualized treatment pathways. Treatment of HCV (unlike HBV) can eradicate the virus and hence is a much more attractive proposition. More recent studies identified powerful viral suppressing polymerase and protease inhibitors which, when used in interferon-free regimens, produce viral clearance in those with difficult-to-treat genotypes and those who have failed therapy previously. The direct-acting antiviral agents (DAA's) have not yet been approved for children but pediatric trials are underway. The decision to treat is based on a number of factors; treatment requires close monitoring and hence should only be undertaken by those experienced in treating children. Treating those with favorable viral genotype and IL28B is expected to lead to viral eradication in greater than 80% of patients. Recommendations of the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition for the Management of Children with Hepatitis C were recently published.

Treatment of hepatitis E is supportive. Prevention rests on improving hygiene; however, a recombinant peptide vaccine was developed and seems to be safe and highly effective in a high-risk population. Further testing in low-risk populations and long-term efficacy is awaited.

### Autoimmune Hepatitis

Prednisone is a potent anti-inflammatory agent usually used as first-line therapy in autoimmune hepatitis. Because of its side effects, particularly on growth, a second immunosuppressive, azathioprine is often added. This allows a reduction or complete weaning of the prednisone. Some children who are refractory to azathioprine and steroids have responded to cyclosporine or tacrolimus.

Prednisone is begun in a dosage of 2 mg/kg/day (maximum 60 mg daily). When evidence of improvement is seen, the prednisone dosage may be tapered at weekly intervals to a dosage that achieves and maintains clinical and biochemical remission. Azathioprine (1–2 mg/kg/day) may be added after evidence of improvement. Toxicity of azathioprine (eg, hematopoietic toxicity) must be monitored for, particularly in children with thiopurine S-methyl-transferase deficiency. The latter can be diagnosed by PCR for the major mutations or by assays of enzyme activity. In addition, adequacy of thiopurine exposure and avoidance of toxicity may be determined by measuring thiopurine metabolites where available. Remission is defined as absence of clinical symptoms, an aminotransferase level no more than 2 times normal, decreasing serum gamma globulin levels, and resolution of the aggressive histologic appearance on a liver biopsy specimen. Duration of therapy, once remission is achieved, is controversial. Generally, once remission is achieved, steroids may be tapered gradually. Long-term treatment with a low-dose steroid or azathioprine is often required.

Clinical remission generally occurs within 3 to 6 months, biochemical remission within 6 to 12 months, and histologic remission within 12 to 24 months. During the steroid taper, the child must be watched at 2- to 4-week intervals for approximately 3 months for evidence of early recurrence of disease. If a recurrence does not manifest within that time, the frequency of observation can be decreased. At least 80% of children seem to achieve initial remission, and although relapses are common, long-term control is usually achieved with continuous immunosuppressive therapy. The child with autoimmune hepatitis and fulminant hepatic failure poses a difficult therapeutic problem. Prednisone and azathioprine have been used in this situation with success; however, liver transplantation may be necessary for survival. The long-term outcome of chronic active hepatitis has been evaluated in several pediatric studies. Most children are likely to have a prolonged survival on minimal long-term immunosuppression.

### Drug-Induced Hepatitis

The profound effects of acetaminophen toxicity can be treated with intravenous *N*-acetylcysteine. In all other cases of suspected drug-induced hepatitis, supportive care is recommended along with discontinuation of the suspected drug.

### Metabolic Liver Disease

The aim of therapy in Wilson disease is copper chelation in a controlled manner. The first-line therapy is penicillamine in most cases; however, penicillamine has significant side effects, including allergies and renal disease, and therapy needs to be closely monitored. Triethylene tetramine hydrochloride (trientine) has been effective in the same dose as penicillamine and is associated with milder side effects. Tetrathiomolybdate in a more stable form recently became available and may be the preferred treatment for neurologic Wilson disease with better control of free serum copper. Zinc may be used as initial therapy in children without clinical disease who are diagnosed incidentally on family screening.

There is no specific therapy for  $\alpha_1$ AT deficiency, and liver transplantation should be considered for end stage liver disease. Carbamazepine was recently shown to decrease the hepatic load of mutant  $\alpha_1$ AT protein and improve fibrosis in a mouse model. This therapy is currently undergoing evaluation in humans. Dietary restriction of galactose is the treatment of choice for galactosemia. Tyrosinemia may be treated with a phenylalanine and tyrosine-restricted diet together with nitisinone ([2-nitro 4-trifluoromethyl benzoyl]-1, 3-cyclohexanedione). Nitisinone is an inhibitor of an early enzyme in the tyrosine degradation pathway and is thought to prevent the accumulation of toxic products, resulting in a clinical improvement in most patients. Although costly, it has been proposed as an alternative to liver transplantation. Whether it will decrease the risk of developing hepatocellular carcinoma remains to be determined. Bile acid replacement therapy is the treatment of choice for inborn errors of bile acid synthesis. Progressive familial intrahepatic cholestasis 1, 2, and 3 have no specific therapy apart from supportive treatment. Liver transplantation may be required for end-stage liver disease. Ursodeoxycholic acid may be used in the treatment of liver disease secondary to cystic fibrosis and may halt disease progression.

### Fulminant Hepatic Failure

Fulminant hepatic failure in children needs to be managed in a setting with liver transplantation expertise. The requirements of liver support must be balanced with the management of fluids, nutrition, and encephalopathy, which is a late and ominous finding in children. It is preferable to transfer a child with severe hepatitis early before intensive care management is required.

### Liver Transplantation

Liver transplantation has improved the outlook for children who have any of a wide variety of severe liver diseases both in terms of mortality and morbidity. Apart from liver failure, indications may include growth failure and intractable itch from cholestasis. The management of the child before transplantation involves aggressive nutritional therapy and prevention of complications such as bacterial peritonitis and variceal hemorrhage, which may adversely affect outcome. Transplantation for chronic liver failure secondary to hepatitis B is complicated by almost 100% recurrence of infection; however, the use of HBIG followed by lamivudine improves the outcome. Recurrence of hepatitis C following transplantation is

around 90%, but transplantation is recommended because recurrent disease is mild in most adults. Recently, recurrence of HCV after transplantation in children has been reported as severe in a small series. Liver transplantation for all causes results in long-term survival rates of over 80% in children. Focus is now directed toward improving morbidity related to immunosuppressive medications and quality of life issues for children and their families.

### WHEN TO REFER

- Children with fulminant liver failure of any cause should be promptly referred to a specialist affiliated with a pediatric liver transplant center.
- Children with uncomplicated hepatitis A can usually be managed by a general pediatrician. However, children with chronic hepatitis B, C, or D should be referred to a pediatric gastroenterologist or infectious disease specialist for consideration for treatment.
- Children with metabolic liver disease, drug-induced hepatitis, or AIH should be referred to a pediatric specialist in metabolic disease or gastroenterology as appropriate.
- Fulminant hepatic failure, defined as a lack of a pre-existing liver disease and severe impairment of hepatic function as evidenced by the following laboratory abnormality: prolonged prothrombin time ( $>4$  seconds over control) that is unresponsive to large doses of vitamin K.
- HbsAg-positive serologic test in children 1 year of age or older.
- Anti-HCV positive serologic test in children 3 years of age or older.
- Any diagnosis of drug-induced hepatitis (unexplained elevation of serum aminotransferases or bilirubin in a child who is taking or recently took any medication).
- Any diagnosis of metabolic liver disease (unexplained elevation of serum aminotransferases or bilirubin in a child) and a positive screening test, such as low ceruloplasmin, low galactose-1-phosphate uridyl transferase, and positive urine-reducing substances.

### WHEN TO ADMIT

- Prolonged prothrombin time ( $>4$  seconds over control) or INR greater than 1.5 in a child with severe hepatitis of any cause
- Acute encephalopathy in a child with severe hepatitis of any cause
- Dehydration requiring intravenous fluid resuscitation in a child with severe hepatitis
- Gastrointestinal bleeding in a child with acute or chronic hepatitis

## Chapter 266

## HERPES INFECTIONS

Lindsey K. Grossman, MD; Yaron Ivan, MD

### DEFINITIONS

Herpesvirus hominis, or herpes simplex virus (HSV), is among the most common agents infecting humans; although 85% to 95% of primary infections may be asymptomatic, in certain circumstances infections can be fatal. HSV is a DNA virus with a protein coat. After an incubation period of 2 to 12 days, the primary infection, if apparent, is usually heralded by constitutional symptoms such as malaise, fever, anorexia, and irritability, and by the classic herpetic enanthem or exanthem. Lesions are painful vesicles, usually several millimeters in diameter, on an erythematous base. After healing and recovering from the initial infection, the infection is not eradicated. Rather, the organism is presumed to remain in a latent phase in the ganglion cells or nerves innervating the region of localized infection. Various stimuli, including sunlight, fever, physical or emotional trauma, or menses, may induce a recurrent infection. Recurrent episodes demonstrate a similar vesicular eruption in the same general anatomic

area as the primary eruption but without concomitant constitutional symptoms.

Pathologically, HSV infection is characterized by the presence of multinucleated giant cells and eosinophilic intranuclear inclusions seen in tissue scrapings taken from the base of a vesicle and stained with Giemsa (Tzanck preparation), Papanicolaou, or hematoxylin-eosin techniques. Herpes infections can be divided definitively into 2 immunologic types that correlate with clinical manifestations—herpes simplex virus type 1 (HSV-1), which tends to be associated with disease above the waist, and herpes simplex virus type 2 (HSV-2), associated with disease below the waist, with sexually related transmission, or with disease acquired neonatally.

## EPIDEMIOLOGIC FACTORS

Studies have shown a sharp rise in the prevalence of antibodies to HSV-1 between 1 and 4 years of age and a slower rise of antibody acquisition between 5 and 14 years of age. Current data suggest that more than 25% of children in the United States have positive serology for HSV-1 by age 7 years.

According to research, HSV-1 seroprevalence has been decreasing in the last few years where HSV-2 (see epidemiologic data in the following text) has been on the rise. It is hypothesized that the decrease in HSV-1 is related to improved hygiene, which has led to delayed (or possibly reduced) exposure to the virus, while the rise of HSV-2 is a result of changes in sexual behavior.

HSV-2 antibody is now detectable in at least 1 of 5 persons 12 years or older nationwide. In 2002, a study demonstrated that 80% to 100% of adults in lower socioeconomic groups, in locations where crowding probably plays an important epidemiologic role, demonstrate antibodies to HSV-1; 30% to 40% or more may be positive for HSV-2. Of persons of higher socioeconomic circumstances, 21% demonstrate antibodies to HSV-2.

## HERPES SIMPLEX VIRUS TYPE 1

### Epidemiologic Factors

Transmission of HSV-1 is presumed to occur via person-to-person respiratory spread and probably involves close contact, such as kissing an infected person. Transmission can occur whether or not the source is symptomatic with an apparent vesicular lesion at the time. The clinical manifestation varies with site of entry, and the clinical diagnosis rarely requires laboratory confirmation.

### Clinical Manifestations

#### Gingivostomatitis

Acute gingivostomatitis is the most common form of HSV-1 seen in children, although about 10% of cases are caused by HSV-2. The peak incidence in the pediatric population is between 6 months and 5 years of age, with a second peak occurring in the early 20s. The disease is characterized by an abrupt onset of fever, irritability, poor feeding, and, 1 to 2 days later, very tender, red, friable mucous membranes surrounding 2- to 3-mm white ulcerations, and severe halitosis. The

vesicular stage is rarely seen, but large, tender anterior cervical and submandibular lymphadenopathy is common. The duration of the illness varies from 5 to 14 days, and the severity ranges from mild to so severe that oral intake becomes negligible, and hospitalization for intravenous hydration may be required. Although this condition is usually benign, bacteremia caused by *Kingella kingae*, part of the normal flora of the mouth, has been observed in a few cases and has been speculated to progress to focal skeletal infection such as osteomyelitis.

### Herpes Labialis

Herpes labialis (or cold sores) represents the most common manifestation of HSV reactivation in the trigeminal ganglia. The most common location of the lesions is on the vermilion border and adjacent skin of the lips, although lesions can occur on the chin, cheeks, and skin around the nose. The lesions usually crust and heal without scarring in 7 to 10 days, but recurrence at the same site is extremely common.

### Herpetic Whitlow

Herpetic whitlow (or herpetic paronychia) is a less common presentation of HSV that may occur as a result of auto-inoculation in children with orofacial herpes and is common in thumb-suckers. It is a result of inoculation at the site of local trauma. This condition is extremely painful and involves herpetic infection of a digit. Although the sore may resemble a bacterial paronychia, it should not be incised. While bacterial paronychia is a confined local infection, herpetic whitlow is sometimes associated with systemic symptoms such as fever and malaise, especially in infants. The disease usually subsides completely within 3 weeks. Unlike bacterial paronychia, which is identified by the presence of suppurative fluid, the lesion of herpetic whitlow typically contains clear fluid in the initial stage that may become cloudy after a week due to accumulation of white blood cells in the lesion.

### Ocular Herpes

Ocular herpes is among the most common causes of corneal blindness in the United States and is estimated to be the cause of 40,000 new cases of severe monocular visual impairment or blindness annually in the world. An estimated 500,000 people in the United States have ocular HSV. HSV-1 has much greater association with ocular pathology than HSV-2 and can manifest as conjunctivitis, iridocyclitis, acute retinal necrosis, and keratitis. However, the primary infection usually involves acute keratoconjunctivitis with intense swelling of the lids but without exudates. Typical herpetic vesicles are often found on the skin surrounding the involved eye. Recurrent disease can be even more severe and may involve superficial or deep epithelial ulceration, stromal damage, or uveitis. Fortunately, treatment is available (see the discussion on treatment in this chapter), but these children should always be referred to an ophthalmologist for care. Indeed, the pediatrician should be aware that devastating results can occur with the use of topical steroid preparations in a probable case of ocular herpes. This

circumstance underlines the necessity of an ophthalmologic consultation before prescribing topical corticosteroids for any use in the eye.

### **Herpes and Sports/Herpes Gladiatorum**

Certain sport activities, such as wrestling and rugby, that result in close skin contact, may increase the risk of HSV skin infection. Wrestlers may acquire herpes gladiatorum (HG) as a result of viral shedding from an infected opponent. In National Collegiate Athletic Association (NCAA) Division I Wrestling, researchers estimate an incidence as high as 20% to 40%. Transmission usually takes place via skin-to-skin contact through areas of skin breakdown.

While these conditions are fairly benign and self-limited, complications such as ocular involvement (blepharitis, follicular conjunctivitis, keratitis, scleritis, and urethritis) can arise and have been described in up to 8% of players in wrestling camps. This is a specific concern because research has shown that the face is the most common site of infection among wrestlers. Perhaps the most serious complication is dendritic keratitis with subsequent corneal scarring, which may lead to permanent blindness.

### **Differential Diagnosis**

The most common ulcerative enanthem to be considered in the differential diagnosis is Coxsackievirus A herpangina. This infection results in lesions very similar in appearance to HSV infection, but is located in the posterior oral cavity, as contrasted with the anterior clustering of herpetic lesions. In addition, Coxsackievirus infections tend to occur during the warm summer months and are less common in the winter season. Other infections to include in the differential diagnosis of HG are localized bacterial, viral, or fungal infections such as impetigo, molluscum and tinea. A critical difference that could help in differentiating among these possibilities is the extensive regional adenopathy observed in HG and the propensity of these lesions to cross the hairline onto the scalp. Infections with varicella, cytomegalovirus, and syphilis should be considered as well, in addition to autoimmune diseases such as Behcet syndrome, Reiter syndrome, and inflammatory bowel disease. Systemic lupus erythematosus and cyclic neutropenia might also be considered in a broader differential. However, with these conditions, the remainder of the clinical presentation would direct the diagnostician to culture for herpes, confirming the final diagnosis if necessary.

### **Complications**

Although HSV-1 infections are usually self-limited, certain human hosts are at more serious risk for contracting or developing severe disease with HSV-1 than are others. Individuals who have deficiencies in cell-mediated immunity, those undergoing immunosuppressive therapy for cancer or transplantation, and those who are extremely malnourished may be more likely to show serious disseminated disease.

Eczema herpeticum is a severe form of a superimposed HSV skin infection in a patient with existing

lesions of atopic dermatitis or other chronic skin diseases. This condition can vary in severity from mild to fatal, and the patient usually experiences constitutional symptoms such as fever and malaise. The lesions, which mostly appear on the head, neck, and trunk, are vesicular and seem to be at the same stage. Wide areas of skin can become denuded, with large fluid, protein, and electrolyte losses, which potentially may be life threatening. Secondary bacterial infection may complicate the condition. Recurrences tend to be milder than the initial infection.

HSV-1 is considered the most common cause of sporadic, fatal encephalitis, with 2 peaks of illness—first between 6 months and 20 years of age and second in patients older than 50 years. Overall, there are 250 to 500 cases per year. The disease is characterized by fever and personality change, and often involves seizures. A rapidly progressive encephalopathy culminates in death in 1 to 2 weeks in more than 70% of untreated cases, and of those patients who do survive, few avoid significant neurologic morbidity. Many will develop developmental delay, behavioral impairment, language disturbance, focal motor deficits, and epilepsy that is often difficult to control. The infection is most often localized to the frontotemporal area, which correlates with symptoms and signs of aphasia, personality changes, and focal seizures. Currently, HSV DNA by polymerase chain reaction (PCR) in cerebrospinal fluid is the most sensitive test to confirm the diagnosis. Treatment has improved the prognosis of this disastrous condition among children, but is most effective when initiated early in the course of the disease.

## **HERPES SIMPLEX VIRUS TYPE 2**

### **Epidemiologic Factors**

As a result of the increase in sexual activity among young adolescents in recent years, pediatricians have been faced with the challenge of diagnosing and treating all types of sexually transmitted infections. The frequency of infection is high and underestimated by clinical history in the adolescent population. The latest HSV-2 data by the Centers for Disease Control and Prevention from March 2010, indicate that the overall national HSV-2 prevalence in persons 14 to 49 years old is as high as 16.2%, but even higher in black women, where it is as high as 39.2%. Genital HSV-2 is of increasing concern to pediatricians not only because of its incidence in adolescent patients, but also because of the potential harm to the offspring of infected mothers.

### **Clinical Manifestations**

Clinically, HSV-2 usually manifests as typical herpetic vesicles on the penile shaft, prepuce, or glans penis in the male patient, and on the labia minora or labia majora, mons, or nearby skin or within the vagina in the female patient. Primary infection is accompanied by significant local pain, burning, or paresthesia and constitutional symptoms of fever and malaise, dysuria, and inguinal lymphadenopathy; recurrent bouts are less severe than initial occurrences. The 5% to 10% of cases of genital herpes associated with HSV-1 are thought to result from orogenital sex.

### Evaluation

Viral culture is, in general, the most sensitive method of diagnosis, but requires several days, depending on the size of the inoculum, for a definitive result. Vesicles, stool, urine, and mucosal surfaces may be used as sites to obtain the culture sample. When lesions are available for scraping, direct detection methods, including fluorescent antibody and immunoperoxidase assays, give a rapid answer, but with lower sensitivity; therefore, a viral culture is still required for confirmation of a negative finding. Tzanck test and Papanicolaou stains are neither specific nor sensitive enough to serve as a screen for HSV. PCR of cerebrospinal fluid is highly specific and sensitive and can discriminate between the HSV-1 and HSV-2 in cerebrospinal fluid; it is the diagnostic method of choice in HSV encephalitis.

## NEONATAL HERPES

### Epidemiologic Factors

Although most neonatal herpes infections are caused by HSV-2, antibodies to HSV-1 are associated with 25% of cases. The prevalence of HSV-2 in healthy American women ranges from 10% to 60%. As many as 50% to 60% of women from lower socioeconomic groups in the United States have antibodies to HSV-2. This proportion translates to an estimated 1,500 to 2,200 infants per year in the United States infected with HSV. Postnatal transmission from a caregiver accounts for approximately 10% of cases.

Infection occurs most commonly during the second stage of labor while the neonate moves through an infected birth canal. Transplacental transmission of HSV, though uncommon, can occur and may induce spontaneous abortion or, in rare cases, congenital anomalies in newborns. In a very small percentage of cases, infection takes place as a result of postnatal exposures to parents or health care workers.

Because HSV is not a reportable disease, the estimated incidence of neonatal herpes in the United States varies with sampling technique and between different populations, ranging between 8 and 60 per 100,000 live births.

The greatest risk of neonatal HSV infection occurs when the mother has contracted primary herpes 2 to 4 weeks before delivery, although the disease may be transmitted to the infant in recurrent cases with or without a clinically detectable herpetic lesion. Transmission of HSV infection to the fetus is most often related to shedding of the virus at the time of delivery. The risk of neonatal herpes for a child born vaginally to a mother with primary genital infection occurring close to delivery is estimated to be 25% to 60%. This is in contrast to a neonate whose mother is shedding HSV because of reactivation of infection acquired during (or before) 20 weeks of gestation, where the likelihood of transmission is significantly reduced and is estimated to be 2% or less. Distinguishing primary versus recurrent infection may be impossible because both may be asymptomatic. Indeed, approximately 75% of infants with HSV infection are born to women without a history of physical or symptomatic evidence of infection. Risk factors for neonatal disease include

a history of a first HSV infection during the third trimester, invasive monitoring of the fetus, delivery at less than 38 weeks of gestation, and maternal age younger than 21 years. Neonatal HSV disease must always be included in the differential diagnosis when a newborn or infant exhibits a skin rash ranging from vesiculopapular to vesiculoulcerative.

### Clinical Manifestations

The presentation of neonatal herpes, similar to other infections in the neonatal period, is nonspecific, at least initially. Presentation is usually acute, with signs and symptoms occurring in the first week or so of life, but can uncommonly occur as late as 3 or 4 weeks of age. Symptoms may include poor feeding, vomiting, fussiness or lethargy, fever or hypothermia, jaundice, and hepatosplenomegaly. Seizures, cyanosis, and apnea may also occur. Most infants, though notably not all, who have neonatal herpes eventually demonstrate a vesicular rash as either individual lesions or clumps of vesicles.

Classically, neonatal HSV infection is classified into three categories based on clinical manifestations.

1. Infants who have disseminated disease involving visceral organs with or without central nervous system (CNS) involvement: These cases comprise up to 25% of neonatal HSV infections and are considered the most lethal, with greater than 80% mortality without treatment and 31% mortality even with prompt administration of high-dose acyclovir. In those patients, AST elevation of more than 10 times the upper limit of normal has been shown to be a poor prognostic sign. Infants who have HSV-1 disseminated infection have poorer outcomes than those who have HSV-2 infection. In disseminated infection, the liver and lungs tend to be most involved, and hepatoadrenal necrosis is virtually always found. Many survivors develop microcephaly, hydrocephalus, intellectual disability, or seizures.
2. Infants with CNS abnormalities without involvement of viscera: These cases represent 30% of neonatal infections. This group of neonates with HSV-2 infections have poorer long-term outcomes, including developmental delay, epilepsy, blindness, or cognitive disabilities. Mortality exceeds 50%, and morbidity exceeds 90% without antiviral therapy. With appropriate antiviral therapy, mortality has fallen to 6%, but morbidity remains high.
3. Infants whose skin, eyes, or mouth (SEM) are involved, but not the CNS or viscera: These cases present with isolated vesicular lesions only and represent 45% of the total. Infants who had SEM involvement before antiviral drugs became available were not expected to die, and only 20% to 30% were left neurologically impaired; many who seemed to have SEM involvement, however, went on to develop disseminated or CNS involvement and to suffer disastrous consequences.

### Prevention

The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists have developed joint guidelines for managing labor in women who have a history of genital herpes. These

guidelines suggest expeditious cesarean delivery if active genital lesions are present at the time of delivery or symptoms that might indicate imminent outbreak, such as vulvar pain or burning, are present. Scalp electrodes should be avoided when the mother is suspected of having active genital HSV infection. In addition, isolation criteria are delineated to protect healthy infants from their HSV-infected mothers, other infected infants, or infected staff. The guidelines also recommend that women with active recurrent genital herpes at or beyond 36 weeks of gestation should be offered suppressive viral therapy, although there are limited scientific efforts to support this plan.

Currently, it is unclear if the risks associated with preterm birth outweigh the risks of HSV infection in women with premature rupture of membranes. Cesarean delivery is not recommended in women with a history of HSV infection without active genital disease during labor.

Neither routine antepartum genital HSV cultures in asymptomatic patients with recurrent disease nor routine HSV screening of pregnant women is recommended.

## TREATMENT

Although no universal cure exists for herpes infections, the prognosis for its many syndromes has improved greatly with currently available therapies. Since the 1980s, acyclovir has become the first-line treatment of choice, with more recent work demonstrating some decreased mortality with prolonged high-dose (60 mg/kg/day divided every 8 hours) intravenous acyclovir.

Treatment should always begin early when there is suspicion of disease. In a multicenter, retrospective cohort study done between January 2003 and 2009, treatment with early acyclovir therapy (within 1 day after hospital admission) was associated with a statistically significant lower mortality rate in comparison to cases in which treatment was initiated after 1 day (6.6% vs 9.5%). Empiric treatment is, therefore, recommended, especially given the low risk for serious side effects of acyclovir.

Current therapy not only emphasizes early treatment, but evidence now suggests that prolonged therapy with oral acyclovir may result in improved long-term outcomes. In a recent study, suppressive therapy with oral acyclovir for 6 months was associated with improved neurodevelopmental outcomes when compared to placebo for neonatal HSV survivors with CNS involvement.

Oral antiviral therapy for first episodes of genital herpes shortens the duration of symptoms and viral shedding and is indicated for at least a 10-day course (Box 266-1). If begun within 1 day of the onset of the first lesion, then episodic therapy may limit the duration and severity of recurrences as well. The same medications have been shown to decrease recurrences by 70% to 80% when used as chronic suppressive therapy in patients with particularly severe or frequent recurrences, though the cost of such therapy may be a limiting factor in its usefulness. Therapy for immunosuppressed individuals with genital HSV may warrant hospitalization and the use of intravenous acyclovir.

### BOX 266-1 Recommended Treatment Regimens for Genital Herpes Infections

#### FIRST CLINICAL EPISODE OF GENITAL HERPES

- Acyclovir 400 mg orally 3 times a day for 7–10 days (max dose in children at 80 mg/kg/24 hr divided q6h to q8h), OR
- Famciclovir 250 mg orally 3 times a day for 7–10 days, OR
- Valacyclovir 1 g orally twice a day for 10 days

Note: Treatment may be extended if healing is incomplete after 10 days of therapy.

#### EPISODIC THERAPY FOR RECURRENT GENITAL HERPES

- Acyclovir 200 mg orally 5 times a day for 5 days, OR
- Acyclovir 400 mg orally 3 times a day for 5 days, OR
- Acyclovir 800 mg orally twice a day for 5 days, OR
- Famciclovir 125 mg orally twice a day for 3–5 days, OR
- Valacyclovir 500 mg orally twice a day for 3 days

#### SUPPRESSIVE THERAPY FOR RECURRENT GENITAL HERPES

- Acyclovir 800–1,000 mg a day, divided in 2–5 times a day for up to 1 year (max dose in children at 80 mg/kg/24 hr divided q6h to q8h), OR
- Famciclovir 250 mg orally twice a day for 1 year, then reassess, OR
- Valacyclovir 500–1,000 mg orally once a day for a year then reassess for recurrences. Patients with <9 recurrences per year may be dosed at 500 mg/dose PO once a day for a year, OR

Derived from Engorn B, Flerlage J. *The Harriet Lane Handbook*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2015: 670–671, 781, 968–969.

Treatment for other herpetic syndromes has also been evaluated. Oral acyclovir can shorten the duration of herpetic gingivostomatitis in children by 6 days if begun within the first 72 hours of illness, with the potential for significant cost savings because of the frequent need for intravenous hydration among children with this syndrome. Only modest efficacy has been shown with treatment of episodic oral herpes; topical antiviral therapy for recurrences has been demonstrated to decrease the duration of symptoms by 1 day or less. Topical antivirals are used to treat superficial keratitis effectively; oral acyclovir may be beneficial in situations of recurrent ocular lesions. Oral antivirals have been shown to prevent herpes gladiatorum at wrestling camps.

Intravenous acyclovir remains the mainstay of treatment for herpes encephalitis. For infants younger than 3 months, the treatment regimen should be continued for at least 21 days; for children older than 3 months, treatment should last 14 to 21 days. Acyclovir has significantly decreased mortality from this condition but has only modestly affected morbidity. Therapy

must be initiated promptly to ensure the most favorable outcome.

Acyclovir resistance has been shown to differ significantly with type of infection and immunologic status of the patient (more common in immunocompromized patients), but this resistance has been repeatedly shown to be fairly low and stable in immunocompetent patients and without adverse clinical outcome. Despite multiple efforts to develop an effective vaccine against HSV, no vaccine exists at this time.

### WHEN TO REFER

- All infants who are thought to have neonatal herpes should be considered potentially critically ill and would benefit from subspecialty involvement to include critical care or neonatology and infectious disease, among others, as indicated.
- Regardless of age, patients who have known or suggested immunosuppression who contract herpes may benefit from subspecialty consultation.
- Children in whom ocular steroid therapy is considered may benefit from ophthalmologic consultation to rule out any possibility of ocular herpes infection.

### WHEN TO ADMIT

- Infants who have suspected or confirmed neonatal herpes must be carefully monitored and treated with intravenous acyclovir.
- All individuals thought to have herpes encephalitis must be hospitalized and treated expectantly with intravenous acyclovir.
- Immunosuppressed individuals with herpes infections may require intravenous antiviral therapy and will require hospitalization.

### Chapter 267

## HUMAN HERPESVIRUS-6 AND HUMAN HERPESVIRUS-7 INFECTIONS

Joshua R. Watson, MD; Asuncion Mejias, MD, PhD, MSCS

### INTRODUCTION

Human herpesviruses type 6 (HHV-6) and type 7 (HHV-7) are ubiquitous, lymphotropic,  $\beta$ -herpesviruses. They are 2 of the known causative agents of roseola infantum, also known as exanthem subitum. It is now understood that in otherwise healthy children, the spectrum of diseases associated with HHV-6 and HHV-7 is far broader than the benign illness of roseola. Furthermore, these viruses commonly reactivate in the immunocompromised host and can potentially be associated with severe disease in these patients.

### CLASSIFICATION

Both HHV-6 and HHV-7 are enveloped, double-stranded DNA viruses that belong to the *Roseolovirus* genus. They were the sixth (HHV-6) and seventh (HHV-7) herpesviruses identified. They can be distinguished from other herpesviruses by DNA hybridization or by reactions with virus-specific monoclonal antibodies.

Two subgroups of HHV-6 are distinguishable by their genetic and epidemiologic characteristics: variant A and variant B. Although the nucleotide sequences are 90% identical, HHV-6B is the variant typically associated with postnatal childhood illnesses, such as roseola. HHV-6A has rarely been associated with disease. The frequency and scope of HHV-7 infections are unclear.

## EPIDEMIOLOGY

Both HHV-6 and HHV-7 are ubiquitous human infections worldwide, with primary infection occurring in childhood. Humans are the only natural hosts. Most children are seropositive for HHV-6 by 2 years of age, with a peak period of acquisition occurring between 6 and 9 months of age (median of 8 months). In a prospective study of 277 children followed from birth through 24 months of age, primary HHV-6 infection was symptomatic in more than 90% of cases and occurred in 40% of children by 12 months of age, increasing to more than two-thirds by 24 months of age. HHV-7 acquisition also occurs in early childhood, although later than HHV-6 and at a slower rate. Nearly all adults are seropositive for both HHV-6 and HHV-7, and maternally derived antibodies are uniformly detected in infants during the first week of life. Congenital infection with HHV-6 but not HHV-7 occurs in approximately 1% of newborn infants.

Like all human herpesviruses, HHV-6 and HHV-7 establish lifelong latency after initial exposure. During the acute phase of the primary infection, they can be isolated from peripheral blood mononuclear cells (PBMCs) and from saliva. Viral DNA can subsequently be found in multiple body sites, including PBMCs, saliva, lung, skin, brain (only HHV-6), and human milk (only HHV-7). Virus is shed in the saliva of asymptomatic individuals and is likely transmitted to susceptible children by this route.

The incubation period is approximately 9 to 10 days for HHV-6 but is not known for HHV-7. Most HHV-6 and HHV-7 infections are sporadic, although family and institutional outbreaks of roseola have been occasionally reported. There is no seasonality to infection. Having at least one older sibling is a risk factor for earlier acquisition of HHV-6.

## CLINICAL MANIFESTATIONS

Clinical manifestations have been well defined for HHV-6. The spectrum of disease remains unclear for HHV-7. Nevertheless, the rate of infection with minor or no signs or symptoms is likely underestimated. Following primary infection, both viruses remain latent and may reactivate. In immunocompetent people, the

manifestations of reactivation are unclear. However, viral reactivation in the immunocompromised host can be associated with severe disease.

### Nonspecific Viral Illness

Frequently, HHV-6 infections manifest as undifferentiated febrile illness and account for about 20% of all emergency department visits for fever in infants 6 to 12 months of age. Body temperature of 39°C to 40°C or higher, typically lasting 5 to 7 days, and irritability are common. In fact, children with HHV-6 infection have significantly higher temperatures, appear sicker, and are more irritable than age-matched children with acute febrile illnesses attributed to other causes. The abrupt onset of high fever is characteristic. Additional symptoms may include fussiness, nonspecific upper respiratory symptoms such as cough or rhinorrhea, inflamed tympanic membranes, rash, vomiting, and diarrhea (see Table 267-1).

In contrast to HHV-6, primary infections with HHV-7 are less frequently recognized. Most primary HHV-7 infections are likely asymptomatic or mild and nondistinctive. In a prospective study, 53% of children were seropositive for HHV-7 by 24 months. However, acute HHV-7 infection, defined by the presence of viremia, was infrequent and detected in only 1% of children presenting with an acute illness. Of those with viremia, 77% had primary and 23% had reactivated HHV-7 infections. High fever followed by seizures, nonspecific febrile illness, upper respiratory tract infections, and gastroenteritis were the most common presenting diagnoses. Whether HHV-7 is the only causative agent for these illnesses or the clinical manifestations result from the ability of HHV-7 to reactivate HHV-6 is a matter of debate.

### Roseola

Roseola infantum—also known as exanthem subitum, 3-day fever, sixth disease, and pseudorubella—is a self-limited, acute illness characterized by fever for 3 days followed by a rash. It was first described in the early 1900s, but HHV-6 and HHV-7 were discovered in 1986 and 1990, respectively. Approximately one-fourth of primary HHV-6B infections in young children in the United States manifest as roseola. HHV-7 causes a

**Table 267-1** Relative Frequency of Presenting Symptoms in Children With Primary HHV-6 and HHV-7 Infections

	HHV-6	HHV-7
Median age (months)	8	26
Fever	++++	++++
Irritability	+++	++++
Upper respiratory symptoms	++/+++	+
Rash	++	+
Vomiting/diarrhea	++	++
Seizures	+	+++

Data derived from Hall CB et al. Human herpesvirus-6 infection in children. A prospective study of complications and reactivation. *N Engl J Med.* 1994;331:432–438; Caserta MT et al. Primary human herpesvirus 7 infection: a comparison of human herpesvirus 7 and human herpesvirus 6 infections in children. *J Pediatr.* 1998;133:386–389; Zerr DM et al. A population-based study of primary human herpesvirus 6 infection. *N Engl J Med.* 2005;352:768–776; Hall CB et al. Characteristics and acquisition of human herpesvirus (HHV) 7 infections in relation to infection with HHV-6. *J Infect Dis.* 2006;193:1063–1069.

similar illness, which may explain the occasional second episode of roseola in a young child. Recognition of the illness is based almost entirely on the observation of a classic clinical course.

Typically, the disease begins with a sudden onset of high fever that usually lasts 3 to 4 days and is often accompanied by irritability. The fever resolves dramatically while an erythematous maculopapular rash simultaneously appears initially on the face, neck, or trunk and then spreads to the extremities. It is usually not painful and does not itch. The macules/papules do not blanch or blister and may be surrounded by a light halo. The rash fades within hours to 2 days. With defervescence, the child seems to have recovered, despite the rash.

The disease may be accompanied by painless posterior auricular, suboccipital, or cervical lymphadenopathy, slight eyelid edema, and Nagayama spots, which are erythematous macules appearing on the soft palate and base of the uvula. Less common features include cough, rhinorrhea, or bulging fontanel. Bulging fontanel is present in one-fourth of patients.

### Central Nervous System Manifestations

#### Seizures

Both HHV-6 and HHV-7 have been associated with febrile seizures and status epilepticus in children. Moreover, some evidence suggests that HHV-6B may play a role in certain types of epilepsy. Overall, primary HHV-6 infection has been found in 10% to 40% of children with febrile seizures within the first 2 years of life and in one-third of patients with febrile status epilepticus. In addition, HHV-6 infection appears to be associated with more severe, atypical, prolonged, and recurrent seizures. Compared with HHV-6, febrile seizures appear to be more common in children with HHV-7 infections. Nevertheless, it is unclear how HHV-6 and HHV-7 contribute to the pathogenesis of febrile seizures. Infections with these viruses may simply serve as common febrile illnesses during the age of highest susceptibility. One small study of children with a first or second febrile seizure showed that the incidence of primary HHV-6 infection was comparable to that in febrile age-matched children without seizures. Additionally, a large prospective study of children presenting with acute febrile illnesses showed similar rates of seizures in those with and without HHV-6.

#### Other Neurologic Manifestations

Occasional cases of meningitis and severe encephalitis attributable to HHV-6 and HHV-7 infections have been reported in children, often associated with long-term sequelae. HHV-6 has also been implicated in cases of progressive multifocal leukoencephalopathy, multiple sclerosis, and other neurologic diseases. In some patients, HHV-6 has been found in brain tissue by immunohistochemical staining. Nevertheless, causation has not been established, and further research is needed.

Cerebrospinal fluid (CSF) abnormalities associated with HHV-6 central nervous system (CNS) disease are infrequent and similar to those found in other infectious causes of meningitis or encephalitis. Brain magnetic resonance imaging (MRI) may be negative or show involvement of the white matter or multifocal

involvement of the hippocampus, amygdala, or temporal lobe. The diagnosis of HHV-6 or HHV-7 as causative agents of CNS disease is often made by the identification of viral DNA in the CSF. However, because these viruses may establish latency, HHV-6 or HHV-7 DNA has been detected in the CSF of infected children with and without seizures.

### Other Manifestations in Immunocompetent Hosts

Different case reports implicate HHV-6 as a cause of chronic and acute hepatitis, ranging from mild to fulminant disease. Although some case reports have relied on seroconversion to define the causative role of HHV-6, others have identified HHV-6 DNA in liver biopsy specimens.

The differential diagnosis for mononucleosis-like illnesses in adults should include HHV-6, which accounts for about 9% of cases. It generally causes mild but prolonged symptoms, lasting up to 3 months.

Both HHV-6 and HHV-7 have been isolated from patients with many other conditions. Among these are pityriasis rosea, lichen planus, Gianotti-Crosti syndrome, and several other dermatologic diseases as well as drug reaction with eosinophilia and systemic symptoms (DRESS), Stevens-Johnson syndrome, immune thrombocytopenic purpura, aplastic anemia, myocarditis, and hemophagocytic syndrome. Because reactivation may occur during acute illnesses, causality of the viruses is difficult to ascertain. The role of HHV-7 in other diseases is even less clear than its association with roseola.

### Congenital Infection

Congenital infection appears to be uncommon. In a large prospective study, congenital HHV-6 infection, defined as viral DNA in cord blood, occurred in 1% of children. Interestingly, although most postnatally acquired HHV-6 infections are caused by the variant B virus, in one-third of the congenital cases the virus detected was HHV-6A. No cases of congenital HHV-7 infection have been reported.

Intrauterine transmission of HHV-6 may occur by either transplacental infection or chromosomal integration in germ cells. HHV-6 has the ability to integrate its genome into human chromosomes and can thus be inherited from one or both parents. Congenital infection exhibits no distinct features or clinical abnormalities in the neonate. It is not known whether clinical manifestations or long-term sequelae may subsequently develop. However, a recent study involving 57 infants with congenital HHV-6 infection demonstrated possible detrimental effects on neurodevelopment at 12 months of age compared with controls without infection.

### Infection in Immunocompromised Patients

Reactivation of HHV-6 may occur during periods of immunosuppression, particularly in patients with depressed T-cell function. Reactivation of HHV-6 has been associated with fever, rash, encephalitis, pneumonia, hepatitis, delayed engraftment, leukopenia, and thrombocytopenia early after transplantation when immunosuppression is highest, especially in hematopoietic stem cell transplant (HSCT) recipients.

Thus, it is challenging to ascertain whether symptoms in immunocompromised patients are directly attributable to HHV-6. Of those illnesses, limbic encephalitis (insomnia, short-term memory loss, hallucinations, and MRI abnormalities in the amygdala and hippocampus) is one of the best-documented manifestations. In addition, HHV-6 viremia has been implicated in graft-versus-host disease. Following solid-organ transplantation (SOT), overt clinical disease directly associated with HHV-6 occurs in less than 1% of patients, but the immunomodulatory effects of HHV-6 infection likely play a role in other associated diseases. As such, HHV-6 is associated with higher rates of rejection and invasive fungal infections, and HHV-6 and cytomegalovirus (CMV) codetection may indicate increased risk for severe CMV disease.

Disease caused by HHV-7 reactivation is not well characterized. Following HSCT, HHV-7 has been reported in cases of encephalitis and myelitis. Like HHV-6, the immunomodulatory effects of HHV-7 infection may predispose transplant recipients to opportunistic infections or severe CMV disease. However, clinical findings have been less frequently reported with HHV-7 than with HHV-6 reactivation. The role of HHV-6 or HHV-7 in human immunodeficiency virus (HIV) infection is inconclusive, with conflicting data regarding whether HHV-6 potentiates or inhibits HIV replication. HHV-6 infection does not seem to affect the progression of HIV to acquired immunodeficiency syndrome (AIDS).

## DIAGNOSIS

Except for roseola, which is the only manifestation that is easily recognized clinically, the diagnosis of HHV-6 and HHV-7 infections is confounded by the intrinsic characteristics of herpesviruses, making it difficult to differentiate acute from past from reactivated infection. During acute HHV-6 infection, white blood cell counts, as well as absolute lymphocyte and neutrophil counts, are decreased compared with other febrile illnesses. In some cases, relative thrombocytopenia is also observed. Results of other routine laboratory tests are typically normal.

Multiple assays for detecting HHV-6 and HHV-7 infection have been developed, including serologic tests, isolation of virus by tissue culture, and detection of viral DNA or RNA by polymerase chain reaction. However, relying on a diagnosis based only on seroconversion, rise in antibody titers, or viral isolation can be misleading. For instance, seroconversion is not always evident in infants because of interference with maternal antibodies. In addition, increases in immunoglobulin G and immunoglobulin M titers have been identified during viral reactivation and therefore do not necessarily indicate new infection. Further, blood viral DNA may be detected with both primary and latent infections, and detection of DNA in other body fluids and tissues does not differentiate between new infection and persistence of virus from past infection. Therefore, a combination of serology (acute and convalescent) and direct viral identification is recommended for the diagnosis when clinically indicated:

- Serologic tests used include immunofluorescent antibody, neutralization, and enzyme immunoassays. These tests do not differentiate between HHV-6A and

HHV-6B and may cross-react with HHV-7. Detection of low-avidity (within 6 weeks of the infection) and high-avidity (>6 weeks) HHV-6 and HHV-7 antibodies may help to confirm recent primary infection. Seroconversion from negative to positive in paired sera provides evidence for recent primary infection.

- HHV-6 and HHV-7 DNA can be detected in blood and CSF in reference laboratories. However, viral DNA detection does not necessarily differentiate between acute infection and viral DNA persistence from past infection. In addition, these assays are not specific enough to differentiate chromosomally integrated HHV-6 infection. The diagnosis of chromosomally integrated HHV-6 is suspected based on the presence of consistently high viral HHV-6 loads in blood and is confirmed by detection of HHV-6 DNA in hair follicles.
- In cases of invasive disease, histopathology and immunohistochemical stains from biopsy specimens may be helpful.

Newly developed diagnostic methods to differentiate latent virus from actively replicating virus may eventually shed light on both the diagnosis and the pathogenesis of diseases associated with HHV-6 and HHV-7.

## DIFFERENTIAL DIAGNOSIS

Roseola is often confused with other exanthematous diseases (see Chapter 236, Contagious Exanthematous Diseases). In rubella, the rash and fever are concurrent, and enlarged lymph nodes are often tender. Coryza, respiratory symptoms, and Koplik spots distinguish rubeola (measles). Enteroviruses and parechovirus may cause a nonspecific exanthem in both older and younger children and are more common in the late summer and fall. Parvovirus B19 causes erythema infectiosum, or fifth disease, which affects school-aged children and involves the face initially with the classic slapped-cheek appearance. Scarlet fever has a more confluent, sandpaper-like rash and is associated with marked pharyngitis. Drug eruptions, especially those resulting from sulfa-containing preparations, are not regularly preceded by fever and tend to be diffuse. Kawasaki disease is accompanied by more prolonged fever along with bilateral conjunctival injection, and the rash is concurrent with the fever.

## MANAGEMENT

In most cases, the management of HHV-6 and HHV-7 infections is supportive and is based entirely on symptoms. Acetaminophen is effective in controlling the fever. Reassuring caregivers that the rash is a sign of recovery often comforts them and may prevent unnecessary office visits.

In the immunocompromised host, the cornerstone of therapy is reduction of immunosuppression to the degree possible. In vitro, HHV-6 is susceptible to ganciclovir, foscarnet, and cidofovir, but the role of antiviral medications has not been extensively studied. Clinically, antivirals have been used most often in immunocompromised subjects to treat HHV-6 encephalitis, with varying success. There are no recommendations for preemptive or prophylactic antivirals for HHV-6 or HHV-7 following HSCT or SOT.

While hospitalized, standard precautions are recommended.

**WHEN TO REFER**

- Primary HHV-6 or HHV-7 infections almost never are clinically recognized until the disease is over.
- Referral is rarely needed except to rule out an alternative diagnosis such as a seizure disorder or treatable encephalopathy or encephalitis.
- Severe clinical symptoms in immunocompromised patients should always be managed in consultation with an infectious diseases specialist.

**WHEN TO ADMIT**

- Hospitalization is indicated in infants with a toxic appearance or if there is CNS involvement such as meningitis, encephalitis, bulging fontanel, or seizures.
- Immunocompromised patients may develop severe HHV-6 or HHV-7 disease, but they are typically hospitalized for their severe clinical presentation—ie, pneumonitis, encephalitis, or suspected graft-versus-host disease—rather than for suspicion of HHV-6 or HHV-7 infection.

**Chapter 268****HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME**

Michael T. Brady, MD; Deborah Persaud, MD;  
William Moss, MD, MPH

Children who have acquired immunodeficiency syndrome (AIDS) were first identified in 1983, 2 years after the description of AIDS in adults. Subsequently it

became clear that AIDS was a manifestation of advanced human immunodeficiency virus (HIV) infection. By the end of 2007, an estimated 4,000 children younger than 21 years were living with HIV infection in the United States. AIDS was the case definition used to describe the collection of opportunistic infections or cancers that were noted in HIV-infected individuals before it was known that HIV was the etiologic agent responsible for the predisposition to these opportunistic conditions. This case definition remains valuable but does not fully describe the effect of HIV infection. AIDS continues to represent advanced stages of HIV infection and results from progressive immune dysfunction.

There are 2 separate HIV viruses: HIV-1, which is the predominant virus responsible for disease in the United States and the rest of the world, and HIV-2, which is primarily detected in patients in West Africa. HIV-2 infection has been detected in the United States in individuals from West Africa or in those who have had sexual contact with individuals from West Africa. Clinical manifestations of HIV infection range from asymptomatic infection to debilitating disease and death. Administration of antiretroviral therapy can considerably modify disease progression. Prepubertal children most commonly acquire HIV infection through maternal–infant transmission, but they also rarely can be infected through receipt of infected blood or blood products and through sexual abuse. At the present time, a substantial number of adolescents are contracting HIV infection through adult behaviors such as unprotected sexual activities and intravenous drug use. Before the widespread use of antiretroviral prophylaxis to prevent maternal–child transmission, as many as 1,800 HIV-infected children were born in the United States annually. Now, fewer than 50 infants are perinatally infected with HIV each year in the United States. The greatest burden of pediatric HIV infection worldwide is in the resource-poor countries of Africa and Asia. However, recent efforts to bring antiretroviral therapy to these areas is already showing evidence of reduced perinatal transmission of HIV and prolonged survival of those who are HIV infected.

Advances in the diagnosis, treatment, and prevention of pediatric HIV infection bring hope to many HIV-infected children, their families, and those who care for them, but a cure remains elusive. The care of HIV-infected children is complex and requires a multidisciplinary team to address the multiple medical, psychological, social, and economic issues that confront HIV-infected children and their families. As HIV infection has been managed more effectively with antiretroviral medication combinations, the psychosocial issues and adverse effects of medical therapy present the greatest challenges to successfully caring for the HIV-infected child.

**TRANSMISSION OF HIV TO CHILDREN**

Perinatal transmission is the most common mode of acquisition of HIV infection among nonadolescent children in the United States. Not all infants born to HIV-infected women acquire HIV infection; estimated perinatal transmission rates in untreated women to

their infants range from 13% to 30%. Appropriate antiretroviral therapy can reduce the rate to less than 2%. Perinatal HIV transmission can occur by 3 mechanisms: transplacental infection in utero, intrapartum infection during labor and delivery, and postpartum infection through mother's milk. Premastication of food for young infants by HIV-infected mothers has recently been noted as a rare cause of HIV infection in young infants. Poor oral hygiene and oral bleeding seem to increase the likelihood of this form of transmission. Before antiretroviral chemotherapy was available to prevent perinatal HIV transmission, intrapartum transmission was the most common mode of transmission in children. High maternal plasma HIV levels (viral load) correlate with increased risk for transmission. Thus, women who have advanced HIV disease or recently acquired infection are more likely to transmit HIV to their newborns. Antiretroviral therapy administered to women during pregnancy and delivery, and to infants during the first 6 weeks of life, greatly reduces the rate of perinatal HIV transmission. Although the total number of perinatal infections has declined, the proportion resulting from intrauterine transmission has increased. This supports the role of antiretroviral therapy and mode of delivery in affecting intrapartum transmission. Perinatal HIV transmission in the United States primarily occurs in women who have poor prenatal care and in women whose viral load is not adequately suppressed because of poor medication compliance or viral resistance.

Routine testing of blood donors for HIV antibody began in March 1985. Children who received blood or blood products before this time were at risk for HIV infection. Children who had hemophilia were at particularly high risk because they received pooled factors from hundreds to thousands of donors. The risk for HIV infection from blood or blood products is now extremely low, estimated to be 1 in 675,000 from a single unit of blood.

HIV transmission through sexual contact occurs in children who are sexually abused or in sexually active adolescents. Behaviors that place adolescents at high risk for HIV infection are initiation of sexual activity at a young age, multiple sexual partners, and unprotected sexual intercourse (vaginal and anal). Given that perinatal transmission has been reduced substantially, adolescents who acquire HIV through adult behaviors represent the most common newly infected pediatric patients.

### **PATHOPHYSIOLOGIC FEATURES OF HIV INFECTION IN CHILDREN**

Perinatal HIV infection occurs during the development and maturation of the immune system. This distinguishes pediatric HIV infection from adult infection and has profound effects on the clinical course, nature, and timing of opportunistic infections and immune responses to immunizations.

HIV infects several different cell types, but the primary target for HIV replication is the CD4<sup>+</sup> T lymphocyte. In addition to the CD4 cell surface molecule, HIV requires a chemokine coreceptor to enter cells. Polymorphisms in chemokine receptors are associated with differing resistance to HIV infection and different

rates of disease progression. Reverse transcription, in which viral DNA is synthesized from viral RNA, is carried out by the enzyme reverse transcriptase. Viral DNA is then transported to the nucleus and integrated into cellular DNA with the help of the viral enzyme integrase, persisting for the life span of the cell. Subsequently, a messenger RNA is produced using human enzymes. This messenger RNA is transported outside the nucleus and is used as a blueprint for synthesizing a large viral polypeptide (HIV proteins and enzymes) that requires cleavage by a viral protease. These newly made HIV proteins and enzymes gather along with HIV RNA to form new viral particles, which are then released from the cell. Currently available antiretroviral therapy works by interfering with the functions of these enzymes: nucleoside and nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors, entry chemokine receptors or fusion inhibitors, and integrase inhibitors.

The number of copies of HIV RNA in plasma can be quantified. Because HIV, like other viruses, is an obligate intracellular parasite, viruses in the plasma represent replicating viruses looking for new host cells. Plasma HIV RNA levels are useful in predicting the rate of disease progression, for modifying antiretroviral therapy, and in understanding viral dynamics. In children who have perinatally acquired HIV infection, HIV RNA levels peak in the first few months of life and decline slowly over several years. Steady-state HIV RNA levels in untreated children are not achieved until 2 to 6 years of age. In contrast, HIV RNA levels in adults decline rapidly to steady-state levels within several months after primary infection. Despite the decline in HIV RNA levels, intense viral replication continues to occur. Combination therapy with reverse transcriptase and protease inhibitors or NNRTIs (highly active antiretroviral therapy [HAART]) block HIV replication and can result in a dramatic decline in virus production and undetectable plasma HIV RNA levels. HIV persists within cellular compartments, however, and a cure is not achievable with current therapies.

Infection with HIV leads to a progressive decrease in CD4<sup>+</sup> T lymphocytes. CD4<sup>+</sup> T lymphocytes are helper T cells that provide stimulatory signals to cells responsible for cellular and humoral immunity and phagocytosis. Qualitative changes in the function of CD4<sup>+</sup> T lymphocytes occur before the decline in number. Because CD4<sup>+</sup> T lymphocytes are crucial to B-lymphocyte function, humoral immunity (antibody production) can be significantly impaired in HIV-infected children, resulting in poor antibody responses to encapsulated bacteria and immunizations, despite increased levels of total immunoglobulins (hypergammaglobulinemia).

### **DIAGNOSIS OF HIV INFECTION IN CHILDREN**

The most important factor in identifying HIV-infected women and children is that the diagnosis be considered. Several risk factors are associated with HIV infection in women of childbearing age, including history of multiple sexual partners, illicit drug use, and sexual contact with

persons at high risk. However, the absence of identifiable risk factors does not exclude HIV infection.

Because maternal HIV antibody will cross the placenta and reach the fetus, detection of HIV DNA or RNA by polymerase chain reaction (PCR) is the preferred method for diagnosing HIV infection in infants (age <18 months). PCR amplifies HIV DNA or RNA sequences and is extremely sensitive in detecting small amounts of virus. Almost all HIV-infected infants have a positive HIV PCR result by 1 month of age, and 40% of HIV-infected infants can be identified in the first 2 days of life. False-positive results have occurred on rare occasions because of laboratory contamination. Positive results should be confirmed by PCR testing of a second blood specimen. Because early detection of HIV infection allows for the initiation of combination antiretroviral therapy in infancy, HIV-exposed infants should be tested by 48 hours of age. A positive PCR result at 48 hours of age signifies intrauterine infection. If negative, repeat PCR testing should be performed at 14 days of age because more than 90% of infected infants will have a positive PCR result by 2 weeks of age. Infants negative for HIV by PCR at 48 hours and at 14 days should be tested at 4 weeks of age and, if negative, again at 4 to 6 months of age. HIV infection is diagnosed by 2 positive HIV PCR tests performed on separate blood samples. Two negative PCR results in a nonbreastfed infant, the first performed at 1 to 2 months and the second at 4 to 6 months of age, make the diagnosis of HIV infection extremely unlikely. Negative HIV PCR results at 2 and 4 weeks of age or 1 negative HIV PCR at 8 weeks of age can be used to provide evidence for presumptive non-HIV infection. This is relevant because it influences the requirement for initiating *Pneumocystis jirovecii* (PCP) prophylaxis. It is not necessary to begin PCP prophylaxis for infants who are presumptively negative. Presumptive negative results need to be confirmed by testing at 4 to 6 months of age. Testing for HIV antibody at 18 months of age is optional.

The HIV enzyme immunosorbent assay (ELISA) detects antibody to HIV and is the appropriate screening test for children older than 18 months. The HIV ELISA has high sensitivity. False-positive results occur but are rare with current tests. Positive ELISA reactions for HIV are confirmed by Western blot analysis. The Western blot detects antibodies to several HIV proteins and is highly specific. False-negative results may occur shortly after primary infection because antibodies to HIV do not achieve detectable levels until 1 to 3 months after infection. Serologic methods should not be used to confirm HIV infection in children younger than 18 months because transplacentally derived maternal antibodies result in a positive HIV ELISA result in infants born to HIV-seropositive women even if the child is not infected. These maternal antibodies can persist for 18 months.

## CLINICAL MANIFESTATIONS OF HIV INFECTION IN CHILDREN

The time from infection to onset of clinical symptoms may be shorter for children who have perinatally acquired HIV infection than for children infected through

blood or blood products, and it is usually shorter than for HIV-infected adults. HIV-infected infants are without symptoms in the neonatal period. Before the widespread use of prophylaxis for PCP and early antiretroviral therapy, a subset of HIV-infected children had rapidly progressive disease and died within the first year of life, often from PCP. Other children remain asymptomatic or have few symptoms for many years, some into adolescence. However, most children who have perinatal HIV infection and are untreated develop symptoms by 2 years of age. High plasma HIV levels and low CD4<sup>+</sup> T-lymphocyte cell counts predict a poor prognosis.

Most of the clinical manifestations attributed to HIV infection can be prevented by appropriate use of antiretroviral medications and careful monitoring of immune status, viral load, and medication toxicity. However, some children may experience complications of HIV infections despite medication compliance and good viral control. Untreated or inadequately treated children, or those who have developed antiretroviral resistance, may exhibit failure to thrive, developmental delay, persistent oral candidiasis, lymphadenopathy, hepatosplenomegaly, chronic diarrhea, recurrent bacterial infections, and recurrent herpesvirus infections. PCP was a common illness found in affected infants before routine prophylaxis of HIV-exposed infants. Laboratory abnormalities often include anemia, thrombocytopenia, and increased immunoglobulin levels.

HIV infection and secondary opportunistic infections can involve all organ systems. Pulmonary disease is common in HIV-infected children. PCP is a fulminant pulmonary infection characterized by tachypnea, cough, hypoxemia, and, most commonly, diffuse alveolar infiltrates on chest radiograph. However, early in the course of PCP in older children, the chest radiograph may be normal or show minimal changes despite significant cough and even hypoxia. Lymphoid interstitial pneumonitis (LIP) is a chronic lung disease of HIV-infected children resulting from lymphoid hyperplasia in the lungs. Children who have LIP may be asymptomatic or may have chronic cough and wheezing. Bilateral, reticulonodular densities are seen on chest radiographs resembling miliary tuberculosis. Children who have LIP are typically older than those who have PCP and often have generalized lymphadenopathy and parotid enlargement.

Central nervous system disease is also more common in HIV-infected children. Microcephaly, developmental delay, spasticity, abnormal reflexes, and gait abnormalities may be present. Characteristic findings on computed tomographic scan include cerebral atrophy and basal ganglia calcifications. Hematologic abnormalities associated with HIV infection include leukopenia, anemia, and thrombocytopenia. Thrombocytopenia may be the presenting illness. In addition, drug-induced bone marrow suppression can follow therapy with zidovudine, co-trimoxazole, and ganciclovir. Hepatomegaly and increases in hepatic transaminases are commonly seen, often in the absence of clinically apparent liver disease. HIV cardiomyopathy may lead to congestive heart failure. HIV nephropathy is a common cause of proteinuria and can progress to nephrotic syndrome. HIV nephropathy is more common in black children.

Chronic diarrhea, resulting from several opportunistic gastrointestinal pathogens, can be debilitating.

Dermatologic conditions include recurrent herpes simplex and varicella-zoster virus infections, severe molluscum contagiosum, chronic fungal infections, atopic dermatitis, and drug-induced eruptions, particularly with co-trimoxazole. HIV-infected children in whom virus replication is not controlled by antiretroviral therapy are often stunted in their growth, and severe wasting may be seen in advanced disease. Malignancies are not as common in HIV-infected children, but lymphomas and leiomyosarcomas can occur.

In 1984, the Centers for Disease Control and Prevention (CDC) developed a classification system based on clinical diseases to categorize HIV infection and AIDS in children. The CDC classification was revised in 1994 to incorporate advances in the understanding of the natural history of HIV infection in children and age-specific CD4<sup>+</sup> T-lymphocyte cell counts (Table 268-1). HIV-infected children are classified into 1 of 4 clinical categories (N, A, B, or C) on the basis of clinical signs and symptoms and into 1 of 3 immunologic categories (1, 2, or 3) on the basis of age-specific CD4<sup>+</sup> T-lymphocyte

cell counts or the percentage of the CD4<sup>+</sup> T-lymphocyte count. However, variability in clinical status exists even within a category (Table 268-2).

### COMMON CLINICAL PROBLEMS IN HIV-INFECTED CHILDREN

Most HIV-infected children who have fever and a normal clinical examination have self-limited febrile illnesses similar to those of HIV-uninfected children. However, as with other immunocompromised children, in HIV-infected children with moderate or severe immunosuppression, fever may indicate a serious infection. A detailed clinical history and careful physical examination, with close attention to general appearance and potential areas of focal inflammation such as skin, ears, sinuses, lungs, and gastrointestinal tract, are essential in the initial assessment of the febrile HIV-infected child. Bacteremia with *Streptococcus pneumoniae* and *Salmonella* can occur in the absence of physical findings. Additional diagnostic studies should be performed on the basis of the child's age, clinical appearance, degree of immunosuppression, and signs and symptoms at the time the patient seeks

**Table 268-1**

**Immunologic Categories Based on Age-Specific CD4<sup>+</sup> T-Lymphocyte Count and Percentage of Total Lymphocytes**

SUPPRESSION	AGE					
	<1 YEAR		1–5 YEARS		6–12 YEARS	
	MCL	%	MCL	%	MCL	%
No evidence of suppression	≥1500	≥25	≥1000	≥25	≥500	≥25
Evidence of moderate suppression	750–1,499	15–24	500–999	15–24	200–499	15–24
Severe suppression	<750	<15	<500	<15	<200	<15

From Centers for Disease Control and Prevention. 1994 Revised classification system for Human Immunodeficiency Virus infection in children younger than 13 years of age. *MMWR*. 1994;43(RR-12):1–10.

**Table 268-2**

**Categories of Human Immunodeficiency Virus Classification in Children**

IMMUNOLOGIC CATEGORY	CLINICAL CATEGORY			
	N	A	B	C
	NO SIGNS OR SYMPTOMS	MILD SIGNS OR SYMPTOMS	MODERATE SIGNS OR SYMPTOMS	SEVERE SIGNS OR SYMPTOMS
1. No evidence of suppression	N1	A1	B1	C1
2. Evidence of moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3

From Centers for Disease Control and Prevention. 1994 Revised classification system for Human Immunodeficiency Virus infection in children younger than 13 years of age. *MMWR*. 1994;43(RR-12):1–10.

care. Laboratory tests to be considered include a complete blood count with differential, large-volume blood culture, chest radiograph, urinalysis and urine culture, and lumbar puncture. Administration of empirical antibiotic therapy is not always necessary and depends on the results of the clinical assessment and laboratory tests, as well as the likelihood of adequate monitoring and follow-up. A third-generation cephalosporin such as ceftriaxone or cefotaxime can be used as empirical antibiotic therapy to provide therapy against both gram-positive and gram-negative bacteria. Ill-seeming children should be hospitalized. Persistent fever in the HIV-infected child can be a diagnostic challenge, but identifiable and treatable causes include mycobacterial infection and drug-induced fever.

*Streptococcus pneumoniae* is the most common bacterial cause of pneumonia in HIV-infected children, who may develop severe disease as a result of infection with common respiratory pathogens such as respiratory syncytial virus, parainfluenza virus, influenza virus, and adenovirus if they have significant immunocompromise. HIV-infected children who have advanced immunosuppression are susceptible to many opportunistic pulmonary pathogens. PCP is the most common opportunistic infection in HIV-infected infants and typically appears at 3 to 6 months of age with cough, tachypnea, and hypoxemia. Early diagnosis and treatment, usually with co-trimoxazole and corticosteroids, is critical. Physicians caring for HIV-infected children must carefully consider the diagnosis of PCP in HIV-infected children who have respiratory tract symptoms. In infants younger than 12 months, neither the CD4<sup>+</sup> cell count nor the CD4 percent is a good predictor of the risk for PCP. However, in children older than 12 months, PCP is unusual in those whose CD4<sup>+</sup> cell count or CD4 percent is normal or who exhibit only moderate immunosuppression, or if the child is receiving appropriate PCP prophylaxis and is adherent with this medication. HIV-infected children who have pulmonary disease and who fail to respond to empirical antibiotic therapy, those who are severely ill, and those who are suspected of having PCP should undergo an invasive diagnostic procedure such as bronchoscopy with bronchoalveolar lavage or lung biopsy.

Persistent diarrhea can significantly compromise the quality of life and nutritional status of HIV-infected children. Infectious causes of diarrhea in HIV-infected children include all of the pathogens of healthy children in addition to numerous opportunistic pathogens. Common parasitic pathogens causing persistent diarrhea include *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium* species, and *Isospora belli*. Cytomegalovirus may cause colitis in children who have advanced immunosuppression. Diagnostic studies should include stool cultures for bacterial and viral pathogens, as well as antigen detection for *Giardia* and *Cryptosporidium* species and possibly ova and parasites. Endoscopy should be considered in refractory cases.

Bacterial and viral pathogens causing meningitis and encephalitis in HIV-infected children are similar to those in nonimmunocompromised children. Opportunistic pathogens causing meningitis and encephalitis

in HIV-infected children who have advanced immunosuppression include *Cryptococcus neoformans*, *Toxoplasma gondii*, and cytomegalovirus. Initial diagnostic studies include analysis of cerebrospinal fluid and brain imaging. Rarely, central nervous system lymphomas can occur.

HIV-infected children with immunocompromise are at increased risk for disseminated varicella and recurrent herpes zoster. HIV-infected children who are susceptible to varicella (no prior natural infection or age-appropriate varicella immunization) should receive a varicella-zoster immunoglobulin preparation (or intravenous immunoglobulin if varicella-zoster immunoglobulin is not available) within 96 hours of exposure to varicella. Disseminated infection can occur with herpes zoster, and oral or parenteral therapy with acyclovir is warranted.

Growth failure is common in untreated HIV infection in children early in the course of disease. The diagnosis of HIV infection should be considered in children who fail to thrive. Frequent measurements of weight and height are important in detecting growth disturbances early and monitoring response to interventions. Effective antiretroviral therapy with suppression of viral replication, as well as nutritional supplementation, is important to the maintenance of growth. However, supplementation with high-calorie foods or formulas often results in increased body fat rather than lean body weight.

Delayed acquisition of developmental milestones or loss of previously acquired milestones is also a common manifestation of untreated HIV infection in children. Effective antiretroviral therapy can minimize or reverse the neurocognitive effects of HIV infection.

## PREVENTING MATERNAL-INFANT HIV VIRUS TRANSMISSION

Identifying HIV-infected women before or during pregnancy is critical in preventing perinatal HIV transmission. Prenatal HIV counseling and testing should be provided to all pregnant women. Initial HIV antibody testing should be performed early in pregnancy and repeated in the third trimester for women at risk for HIV infection, such as those with a history of multiple sexual partners, illicit drug use, or a sexual partner at risk for HIV infection. Administering zidovudine to women during pregnancy and labor and to infants for the first 6 weeks of life has been shown to reduce perinatal HIV transmission by two-thirds (26% to 8%). This regimen was previously the standard of care for HIV-infected pregnant women and their newborns. Other regimens should be used based on the clinical, immunologic, and viral status of the mother. In general, HIV-infected pregnant women should receive the optimal medical and antiretroviral therapy required for their own health. For those women for whom deferral of antiretroviral therapy is acceptable because of normal immune status, antiretroviral therapy is still indicated during pregnancy as a means to optimally suppress the HIV viral load in order to prevent maternal-infant HIV transmission. Early identification of HIV-infected pregnant women also allows for appropriate care of the mother,

avoidance of ongoing HIV exposure of the infant through human milk, and early institution of PCP prophylaxis for the infant at 4 to 6 weeks of age. Cesarean delivery can also reduce the risk for perinatal HIV transmission. All HIV-infected pregnant women should be counseled concerning the benefit and risks of cesarean delivery. For women with viral loads consistently greater than 1,000 copies/mL, it should be strongly encouraged. For women with viral loads less than 1,000 copies/mL, the benefits of cesarean delivery may not outweigh the risks.

### CARE OF THE HIV-INFECTED CHILD

Proper care of HIV-infected children requires a multidisciplinary team including pediatricians, experts in antiretroviral therapy, nutritionists, physical therapists, pharmacists, psychologists, social workers, and outreach workers. The pediatrician should rely on HIV care providers for the management of antiretroviral drugs.

#### Immunization of the HIV-Infected Child

Immunizations are generally safe for HIV-infected children, although the immune suppression caused by HIV results in less assurance of protection after immunization than in non-HIV-infected children. However, the small risk for serious complications from live viral vaccines has led to special recommendations for HIV-infected children. Live oral rotavirus vaccine should not be administered to severely immunocompromised children. However, HIV-exposed infants with testing that does not support HIV infection may receive their initial dose of live oral rotavirus vaccine before documentation that the infant is not infected (negative PCR after 4 months of age).

Toxoids, subunit vaccines, inactivated vaccines, and recombinant vaccines are not associated with increased risk for complications in HIV-infected children. Vaccines in these categories include diphtheria and tetanus toxoids, acellular pertussis vaccines, inactivated polio virus vaccine, *Haemophilus influenzae* type b, meningococcal and pneumococcal conjugate vaccines, inactivated influenza vaccine, and hepatitis A and B vaccines. The human papillomavirus vaccine should be given to HIV-infected females and males at 11 to 12 years of age with catch-up to age 26 years. These vaccines should be administered to HIV-infected children according to the routine immunization schedule. Because of an increased risk for invasive infection with *Streptococcus pneumoniae*, immunization of HIV-infected children with pneumococcal conjugate vaccine is particularly important. HIV-infected children may develop lower antibody titers than healthy children after immunization and are more likely to lose protective antibody earlier. The Infectious Diseases Society of America is developing guidelines that should assist physicians determining optimal primary series and booster dosing of vaccines for HIV-infected children.

Live virus vaccines, such as varicella, and measles, mumps, and rubella vaccines, may result in infections and diseases from vaccine virus in severely immunocompromised HIV-infected children, although the risk is quite small. After the report of a death caused by

measles vaccine virus after immunization, advisory groups in the United States recommended withholding measles vaccine from HIV-infected children with severe immunosuppression, defined as CD4<sup>+</sup> T lymphocytes less than 15%. Measles-mumps-rubella (MMR) vaccine should be administered to HIV-infected children at 12 months of age and a second dose at 1 month (minimum of 28 days) later unless the children are severely immunocompromised (CD4<sup>+</sup> <15%). As with other vaccines, the immune response to measles vaccine in HIV-infected children may be poor, and vaccinated children may remain susceptible to measles virus infection despite prior immunization. The combination vaccine MMRV should not be given to HIV-infected children. Serious complications after mumps or rubella immunization have not been reported.

Live varicella virus vaccine also is recommended for HIV-infected children on the basis of their degree of immunosuppression and symptoms. The American Academy of Pediatrics Committee on Infectious Diseases recommends varicella vaccine at 12 months of age and a second dose 3 months later for asymptomatic and mildly symptomatic HIV-infected children who have CD4<sup>+</sup> T-lymphocyte percentages of 15% or more. Serious adverse events after administration of varicella vaccine to HIV-infected children are rare.

#### Antimicrobial Prophylaxis

Because of the high mortality rate associated with PCP in early infancy, PCP prophylaxis should be administered to HIV-exposed infants beginning at 6 weeks of age, if HIV infection status is not established. Criteria for discontinuing PCP prophylaxis are age related and include evidence of immune reconstitution for at least 3 months on effective antiretroviral therapy. Lifelong PCP prophylaxis is recommended for children who have a history of PCP, despite immune reconstitution. Prophylaxis is continued until 12 months of age or until the diagnosis of HIV infection has been excluded. For children 1 to 5 years of age, PCP prophylaxis is administered if the CD4<sup>+</sup> T-lymphocyte cell count is less than 500 cells/mm<sup>3</sup> and for children 6 to 12 years of age if it is less than 200 cells/mm<sup>3</sup>. The recommended regimen is co-trimoxazole taken orally 3 days a week. Alternative regimens include dapsone or pentamidine.

HIV-infected children who have recurrent oral candidiasis may benefit from antifungal prophylaxis with oral nystatin, clotrimazole, or fluconazole. Oral azithromycin weekly or clarithromycin daily for prophylaxis against *Mycobacterium avium-intracellulare* infection is indicated in children based on age-related CD4<sup>+</sup> cell counts (children >6 years with CD4<sup>+</sup> cell counts <50 cells/mm<sup>3</sup>; children 2 to 5 years with CD4<sup>+</sup> cell counts <75 cells/mm<sup>3</sup>; children 1 to 2 years with CD4<sup>+</sup> cell counts <500 cells/mm<sup>3</sup>; and infants <1 year with CD4<sup>+</sup> cell counts <750 cells/mm<sup>3</sup>). Immunoglobulin should be provided to susceptible (no age-appropriate measles immunization) HIV-infected children within 6 days of exposure to a person who has measles. Measles immunization should be delayed 6 months after receipt of immunoglobulin.

### Antiretroviral Therapy

The treatment of HIV infection with antiretroviral drugs is complex. Management of antiretroviral therapy should be directed by a specialist who has knowledge of the mechanisms of action of antiretroviral agents, potential toxicities, drug interactions, and cross-resistance patterns. Because most children acquire HIV infection during or near the time of birth, antiretroviral therapy should be initiated in infancy. Although early therapy restores immunologic function, the risks for drug toxicity and acquisition of drug-resistant virus are increased. Decisions to initiate early therapy require balancing the benefits and risks. Combination antiretroviral therapy is indicated for all infants diagnosed with HIV infection in the first year of life, regardless of clinical, immunologic, or virologic status. For children diagnosed after 12 months of age, the decision to start treatment should be based on clinical symptoms, plasma HIV RNA levels, and CD4<sup>+</sup> T-lymphocyte counts.

The choice of antiretroviral regimen for children is based on several factors, including the availability of pediatric formulations, potential drug interactions, the frequency of drug dosing, and potential interactions with other medications. Before therapy begins, the child's clinical, virologic, immunologic, and nutritional status should be documented. Neuropsychometric testing should be performed in children with suspected neurodevelopmental deficits. Baseline laboratory studies should include a complete blood count with differential, liver function tests, a CD4<sup>+</sup> T-lymphocyte cell count, and plasma HIV RNA level.

Combination antiretroviral therapy consists of a protease inhibitor or NNRTI in combination with 2 or more nucleoside reverse transcriptase inhibitors (NRTIs). Protease inhibitors that may be used in children include lopinavir/ritonavir (preferred), nelfinavir, ritonavir (alone), amprenavir, and indinavir. Lopinavir/ritonavir, nelfinavir, ritonavir, and fosamprenavir are available in liquid formulations. Atazanavir, darunavir, tipranavir, and saquinavir are available protease inhibitors with insufficient data in children to recommend for initial therapy at this time. They may be used in adolescents. Preferred 2-NRTI backbones include abacavir plus lamivudine or emtricitabine, didanosine plus lamivudine or emtricitabine, tenofovir plus lamivudine or emtricitabine, and zidovudine plus lamivudine or emtricitabine. Alternate 2-NRTI backbones include zidovudine plus abacavir and zidovudine plus didanosine. In special circumstances, stavudine plus lamivudine or emtricitabine could be used as the 2-NRTI backbone. Stavudine plus didanosine should not be used or should be used only with substantial caution because of their potential synergistic toxicities. Several combinations are not recommended either because of antagonism (stavudine-zidovudine) or because of overlapping toxicities. The NNRTIs nevirapine, delavirdine, and efavirenz can be used in combination with the NRTIs. Nevirapine is preferred in children younger than 3 years, and efavirenz is preferred in children 3 years or older. Efavirenz is only available in capsule form.

Regimens containing etravirine, maraviroc, raltegravir, and enfuvirtide (T-20) should not be used in initial treatment regimens for children. However, in children who have failed other regimens because of antiretroviral resistance, these medications may provide the only options available. They should be used with caution in children because safety and dosing are not well established for children.

The following are antiretroviral regimens or components that should *never* be offered as treatment of HIV infection in children: monotherapy; 2 NRTIs alone; tenofovir plus abacavir plus lamivudine or emtricitabine; tenofovir plus didanosine plus lamivudine or emtricitabine; dual NNRTI combinations; combinations of lamivudine plus emtricitabine; combinations of stavudine plus zidovudine; and unboosted saquinavir, darunavir, or tipranavir (these protease inhibitors requiring boosting with ritonavir because of poor bioavailability). Efavirenz should never be given in the first trimester of pregnancy or to sexually active adolescent girls of childbearing potential when reliable contraception cannot be ensured. Nevirapine should not be initiated in adolescent girls with CD4<sup>+</sup> cell counts of >250 cells/mm<sup>3</sup> or adolescent boys with CD4<sup>+</sup> cell counts of >400 cells/mm<sup>3</sup>.

Common side effects of NRTIs are anemia and neutropenia with zidovudine, pancreatitis with didanosine, peripheral neuropathy with didanosine and stavudine, and an influenza-like hypersensitivity reaction with abacavir. Rechallenge with abacavir after a hypersensitivity reaction can be fatal. Common side effects of the NNRTIs nevirapine, delavirdine, and efavirenz are rashes and hepatitis. Efavirenz can cause nightmares, hallucinations, confusion, and impaired concentration. Gastrointestinal symptoms are the major side effects of protease inhibitors. Long-term complications of combination antiretroviral therapy include lipoatrophy, lipodystrophy, hypercholesterolemia, metabolic syndrome, and bone demineralization.

Adherence to complex drug regimens can be hindered by the large number or volume of medications, poor palatability, varied dosing schedules, and different effects of food on drug bioavailability. Mixing the drugs with foods, such as peanut butter or ice cream, may improve adherence in children. Behavioral therapy, begun before combination therapy is initiated, can be helpful in designing a routine medication schedule, teaching parents and caregivers methods to improve adherence, and teaching the child techniques for swallowing unsavory medications. Gastric tubes may be necessary and helpful to ensure medication adherence in children because of medication taste or volume problems.

Strict adherence to the treatment regimen is essential for the prevention of drug resistance. Because of cross-resistance, resistance to one drug can limit the effectiveness of other drugs of the same class. Viral sequences obtained from plasma samples can be tested for drug resistance mutations and for susceptibility profiles to guide treatment decisions. Plasma HIV RNA levels should be measured 4 weeks after the child has started therapy to assess response. The frequency of follow-up visits depends on many factors, including

the child's clinical status and expected compliance with therapy, but should include measurements of HIV RNA levels and CD4<sup>+</sup> T-lymphocyte counts.

### **Drug Interactions With Antiretroviral Therapy**

HIV protease inhibitors, as well as the NNRTIs, are metabolized in the liver by a cytochrome P-450 enzyme. Protease inhibitors have the potential to inhibit this enzyme and interfere with the metabolism of many other drugs. Protease inhibitors also can act as potent inhibitors of 2 other P-450 enzymes active in the metabolism of analgesics, beta blockers, and phenytoin. Ritonavir can stimulate glucuronidation, thus decreasing the concentration of drugs metabolized by this pathway, including sedatives such as lorazepam and the narcotics morphine and codeine.

Many drugs that have altered metabolism because of protease inhibitors are used in pediatric emergencies, including narcotic analgesics, anticonvulsants, antiarrhythmics, calcium channel blockers, and corticosteroids. These drugs should be used with caution in children receiving protease inhibitors. Drugs that have narrow therapeutic margins require particularly careful monitoring for adverse effects and measurement of drug concentrations. Drugs contraindicated for use with protease inhibitors include meperidine, midazolam, astemizole, terfenadine, cisapride, and rifampin. Additional medications may be added to this list based on new experience and reports.

A number of other medications often prescribed for HIV-infected children are inhibitors of cytochrome P-450 enzymes, including ketoconazole, itraconazole, clarithromycin, and erythromycin. Inhibition of cytochrome P-450 enzymes by these medications may lead to an increase in the plasma concentration of protease inhibitors. Dose reduction of the protease inhibitor may be required. Conversely, inducers of the cytochrome P-450 enzyme system are also commonly prescribed for HIV-infected children. Antimycobacterial drugs (rifampin, rifabutin), anticonvulsants (phenobarbital, phenytoin, carbamazepine), and glucocorticoids (dexamethasone) are inducers of cytochrome P-450 enzymes. Increased metabolism of protease inhibitors may result in subtherapeutic levels, with the potential emergence of drug resistance.

### **POSTEXPOSURE PROPHYLAXIS AFTER COMMUNITY NEEDLESTICK INJURIES**

Parents, caretakers, and physicians often are most concerned about transmission of HIV after accidental injury from a discarded needle. However, no consensus or recommendation is available to guide management in such circumstances. The risk for HIV transmission after occupational exposure to HIV-infected blood is 0.3%. Most experts agree that the risk after community needlestick injury is lower than the risk after occupational exposure. Factors to be considered in the use of antiretroviral agents for postexposure prophylaxis after community needlestick injuries include the potential risk for HIV transmission, drug toxicities, and the ability and willingness of the family to adhere to therapy. Regimens

for occupational postexposure prophylaxis may be followed.

### **CHILD CARE AND SCHOOL FOR THE HIV-INFECTED CHILD**

Because the risk for HIV transmission seems to be negligible, HIV-infected children should not be restricted from attending child care or school. Special consideration may be warranted for children who have unusual risk factors for transmission, such as frequent biting or scratching, severe dermatitis, or bleeding disorders. In such circumstances, the pediatrician should assess the need to protect other children.

### **HIV-INFECTED ADOLESCENT**

An increasing number of adolescents are infected with HIV through unprotected sex. Because the onset of AIDS occurs years after sexual transmission, AIDS in young adults reflects acquisition of HIV during adolescence. Pediatricians caring for adolescents must ensure that their patients have knowledge of the risks for acquiring HIV and other sexually transmitted infections through unprotected sex and be counseled on safe-sex practices.

Primary HIV infection in adolescents and adults is often accompanied by a mononucleosis-like illness characterized by fever, sore throat, lethargy, and lymphadenopathy (seroconversion syndrome). Because HIV antibodies take several months to achieve detectable levels, nucleic acid-based assays (PCR) should be used to diagnose symptomatic primary HIV infection.

### **ROLE OF THE PEDIATRICIAN IN THE CARE OF HIV-INFECTED CHILDREN**

The pediatrician plays a critical role in the care of HIV-infected children and their families. Responsibilities include diagnosing HIV infection; providing well-child care, including monitoring growth and development and administering immunizations; coordinating care among the multiple specialties and services, including experts in antiretroviral therapy, developmental and psychological assessment, nutritional support, and dental care; managing common medical problems; and directing the family to social and financial support services.

Many parents or guardians are not willing to tell the child that he or she is infected with HIV. However, most children are made aware of their illness through frequent medical visits and medications. The pediatrician is often in the best position to promote and assist with disclosure. Appropriate disclosure tailored to the child's cognitive level is helpful in alleviating guilt and allows for discussion between the child, caregivers, and health care professionals. Uninfected siblings of HIV-infected children also are emotionally affected by the diagnosis and should be included in support groups and counseling.

The pediatrician also plays a critical role in providing advice and support as the child nears death, helping the family interpret the complexities of critical care and decisions on the appropriateness of heroic

interventions. In some circumstances, the pediatrician may even be able to assist the family in caring for the dying child at home if critical care is deemed futile. After the death of the child, the pediatrician should continue to support the family through the grief process. Because many pediatricians invest much time and emotional energy in caring for an HIV-infected child, many take the opportunity to express their sympathy by attending the child's funeral. This can be an important gesture for both the family and the pediatrician.

## Chapter 269

# HYDROCEPHALUS

Robert M. Lober, MD, PhD; Sonia Partap, MD, MS

### INTRODUCTION

Hydrocephalus is a condition of excessive intracranial cerebrospinal fluid (CSF) volume resulting in increased intracranial pressure, ventriculomegaly, or macrocephaly in children, and may be congenital or acquired. Treatment is surgical diversion of CSF, either by alleviating the obstruction, rerouting the flow, or artificial shunting to extracranial cavities capable of absorbing excess fluid. In chronic cases, patients may have a good quality of life punctuated by unexpected failures of therapy, repeated medical evaluations, and surgical procedures. Adverse effects on brain function can range from mechanical distortion or impaired cerebral blood flow to changes in metabolism and neurotransmission.

### FOUNDATION

#### Definition

Hydrocephalus refers to an excessive CSF volume that disrupts normal brain function. Its manifestations are specific to developmental stages (eg, association with abnormal brain development in the fetus, ventriculomegaly or macrocephaly in the neonate, and intracranial hypertension in older children with closed cranial sutures). It is not synonymous with ventriculomegaly. Hydrocephalus can occur with ventricles of normal size that lack the compliance required for expansion in response to higher pressure, whereas ventriculomegaly refers to large ventricular size. Ventriculomegaly might be a more appropriate term than hydrocephalus in cases for which intracranial pressure is not measurable. Hydrocephalus *ex vacuo* specifically refers to an enlargement of the ventricles resulting from brain atrophy without increased intracranial pressure.

#### Epidemiology

The reported incidence of congenital hydrocephalus is 7 per 10,000 births (live and stillborn), with approximately 10% involving additional, multiple congenital abnormalities. In the United States, hydrocephalus results in approximately 40,000 pediatric hospital admissions per year, with estimated total hospital charges of around \$2 billion.

#### Etiology

The traditional view and classification of hydrocephalus relies on a paradigm of CSF flow obstruction between the site of production within the ventricles and sites of drainage into the dural venous sinuses. This is an appropriate model when there is an identifiable blockage on imaging studies (eg, a posterior fossa tumor or congenital aqueductal stenosis). On the other hand, cases of hydrocephalus may occur

following infection or hemorrhage in the absence of an obvious flow obstruction. These may be disorders of fluid absorption, but a growing body of literature suggests that they result from abnormal CSF pulsations and brain compliance. In some cases, the lack of an appropriate gradient between intracranial and central venous pressure can result in poor CSF absorption, as with small babies or patients undergoing large craniectomies for stroke or trauma, where intracranial pressure cannot exceed atmospheric pressure and thus CSF fails to be reclaimed into the venous system.

L1 syndrome is the most common genetic form of congenital hydrocephalus, arising from 1 of more than 200 possible *L1CAM* gene mutations on Xq28 that disrupt the normal production of cell adhesion molecules. Children with L1 syndrome have the associated findings of intellectual disability, adducted thumbs, aqueductal stenosis, spastic paraplegia from pyramidal tract hypoplasia, and agenesis of the corpus callosum.

#### Classification

Hydrocephalus has most often been classified as noncommunicating or communicating depending on whether there is an identifiable point of obstruction to CSF circulation (Table 269-1). This classification scheme has proved to be inadequate in patients shunted for hydrocephalus in infancy who later develop severe intracranial hypertension without ventriculomegaly on occasions of shunt failure. Thus, some authors have advocated a more specific classification system based on the site of obstruction, though in some cases aberrant CSF pulsations and subarachnoid compliance may cause hydrocephalus.

#### Risk Factors

Posthemorrhagic ventricular dilatation occurs in one-third of premature infants with intraventricular hemorrhage, caused either by hydrocephalus *ex vacuo* from encephalomalacia or by intracranial hypertension. Approximately 15% of these require permanent CSF diversion.

Infection is cited often as a predisposing factor for hydrocephalus, although the actual risk following infection is not well documented. Hydrocephalus occurs with an estimated incidence of 31% among survivors of neonatal meningitis. Radiographic findings of ventriculomegaly have been attributed to cytomegalovirus (CMV), toxoplasmosis, syphilis, and varicella, along with rare case reports of lymphocytic choriomeningitis and mumps viruses, the latter of which have been associated with acquired aqueductal stenosis. In regions endemic for tuberculosis, hydrocephalus is among the most common complications of tubercular meningitis, occurring in more than 70% of cases. Infection is also a risk factor for multiloculated (complex) hydrocephalus, which occurs in rare cases when the ventricular system becomes trabeculated and encysted.

Mass lesions arising at any stage of childhood are risk factors for acute hydrocephalus through obstruction of the ventricular system. Congenital malformations of the posterior fossa, including the genetically

**Table 269-1** Classification of Hydrocephalus

NONCOMMUNICATING HYDROCEPHALUS	COMMUNICATING HYDROCEPHALUS
<b>CONGENITAL CAUSES</b> Atresia of the foramen of Monro Chiari malformations Dandy-Walker syndrome Intracranial cysts Aqueductal stenosis Rare genetic syndrome (L1 syndrome)	<b>CONGENITAL CAUSES</b> Dandy-Walker syndrome Chiari malformations Encephalocele Intracranial cysts Subarachnoid villi noncompliance
<b>ACQUIRED CAUSES</b> Intraventricular hemorrhage Infectious (bacterial/fungal) Chemical Neoplastic/mass	<b>ACQUIRED CAUSES</b> Infectious (bacterial/fungal) Chemical Leptomeningeal neoplasms Subarachnoid hemorrhage/siderosis

heterogeneous Dandy-Walker syndrome and other similar cerebellar hypoplasias, are associated with up to 4% of all hydrocephalus cases. These may include cysts or stenotic foramina that cause discontinuities in the ventricular system, although these potential mechanical obstructions are not universally accepted as the etiology. Similarly, for reasons that are still not entirely clear, hydrocephalus occurs in 80% to 90% of patients with myelomeningoceles.

## DIAGNOSIS

### Signs and Symptoms

Acute hydrocephalus may present with rapidly worsening symptoms, in which case the neurologic examination should be focused on whether the patient has a level of consciousness sufficient for airway protection and whether immediate neurosurgical consultation for CSF diversion is warranted prior to any further evaluation. In more chronic conditions, symptoms are dependent upon the child's stage of development (Table 269-2).

Routine pediatric physical examinations may reveal a slow compensatory cranial expansion accompanied by delayed suture closure, frontal bossing of the forehead, and prominent scalp veins, but no neurologic deficits. In older children, gradual cognitive and motor decline becomes apparent with missed developmental milestones. Loss of visual acuity or fields, cranial nerve palsies, and acute papilledema can occur before ventricular dilatation, although a normal examination does not rule out intracranial hypertension. Longstanding hydrocephalus may result in optic atrophy and amblyopia, which may confound the evaluation for acute decompensation in affected patients.

### Differential Diagnosis

In the absence of signs or symptoms of intracranial hypertension, a head circumference 2 standard deviations above the mean or above the 98th percentile for age is usually caused by benign isolated macrocephaly or familial macrocephaly. This presents in an autosomal dominant pattern within a family and is associated with normal intellectual development. In some cases, these children may have mild suture diastasis

that is not associated with intracranial hypertension. Imaging studies in the first months of life may demonstrate prominent bifrontal subarachnoid spaces with widened interhemispheric fissures, prompting the designation *benign external hydrocephalus* for this normal variant by some authors.

A child's head may seem large despite normal circumference because of frontal bossing (eg, in cases of cranial hyperostosis, rickets, and liposomal storage disorders). Bilateral frontal and parietal prominence resulting in a "box-shaped" skull may herald chronic subdural hematomas (eg, with nonaccidental trauma, coagulopathy, or glutaric aciduria type I). Relative macrocephaly (less than 2 standard deviations above the mean, but disproportionately large relative to height and weight) may be caused by short stature, which could be related to intrauterine growth restriction, achondroplasia, or other skeletal dysplasias.

Macrocephaly is a common reason for a medical genetics referral. Consultations must include evaluation for neurocutaneous and systemic stigmata of relevant syndrome associations, such as neurofibromatosis and lysosomal storage diseases. Syndromes of systemic overgrowth (such as Sotos, Simpson-Golabi-Behmel, Bannayan-Ruvalcaba-Riley, Weaver, Fragile X, and macrocephaly-cutis marmorata telangiectatica congenita), or of macrocephaly without somatic overgrowth (such as Opitz-Kaveggia, Greig cephalosyndactyly, acrocallosal syndrome, and Gorlin syndrome), must be considered.

### Diagnostic Approach

The appropriate diagnostic approach includes a careful medical and family history, with attention to developmental milestones, intellectual and academic ability, visual disturbances, headaches, neurologic symptoms, and stigmata of syndromic associations. The examination should include objective measurements of head circumference, height, and weight, along with fundoscopy, visual acuity and fields, assessment of fontanelles and sutures, and a complete neurologic and physical examination. Imaging studies should be appropriate for developmental stage and should be used to verify or rule out clinical suspicions. In some cases, a multidisciplinary approach with

**Table 269-2** Clinical Signs and Symptoms in Pediatric Hydrocephalus

AGE GROUP	SYMPTOMS	SIGNS
Premature infants	Attacks of apnea or bradycardia	Tense and non-pulsatile anterior fontanel Distended scalp veins Abnormal head contour with prominent forehead Rapid (>1 cm/wk) skull circumference increase
Full-term infants	Irritability Vomiting Drowsiness	Full or tense anterior fontanel Distended scalp veins Frontal bossing Widening of cranial sutures Cracked pot sign on percussion (Macewen sign) Macrocephaly Poor head control Sixth cranial nerve palsy Setting sun sign (appearance of sclera above iris) Impairment of upward gaze
Older children	Steady or progressive headache Vomiting Blurred vision, diplopia Lethargy Personality and behavior changes	Papilledema Spasticity, more in lower limbs Sixth cranial nerve palsy Neuroendocrinopathies

neurologic, ophthalmologic, neurosurgical, and medical genetics referrals is warranted.

### Laboratory Findings

Laboratory studies are most useful in cases of suspected infection, which may alter therapy decisions. Cultures and cytology derived from CSF may be helpful in diagnosing active central nervous system (CNS) infection, in which case placement of a permanent shunt is usually deferred for a temporizing measure such as medical management, serial ventricular or lumbar taps, or ventriculostomy for continuous external CSF drainage.

### Imaging

Skull radiography may demonstrate open sutures and erosion of the dorsum sellae, but is more of historical interest and not generally used for definitive diagnosis. The diagnosis can be made with ultrasonography in the neonatal period, as the open fontanelles provide a corridor for insonation. In older children, computed tomography (CT) was previously the first-line modality used to demonstrate the typical findings of ventriculomegaly, interstitial periventricular edema, and sulcal effacement. Calvarial thinning or delayed suture closure may be present in chronic cases. It should be noted that many centers are replacing CT with magnetic resonance imaging (MRI) as a first-line modality in order to avoid excessive radiation exposure with repeated scans.

On initial evaluation, MRI is recommended to evaluate for aqueductal stenosis and arachnoid adhesions that would not be obvious on CT. This modality is also appropriate for assessing causes of macrocephaly associated with leukoencephalopathy (eg, Alexander and Canavan disease, childhood ataxia with central hypomyelination/vanishing white matter disease, glutaric aciduria type I, L-2-hydroxyglutaric aciduria, and

megalencephalic leukoencephalopathy with subcortical cysts). Prenatal MRI scans are also increasingly available when prenatal ultrasounds are worrisome.

### Diagnostic Procedures

In the absence of space-occupying mass lesions, lumbar puncture may be helpful for identifying increased intracranial pressure. In patients with known shunted hydrocephalus, access to the shunt reservoir via a subcutaneous puncture can allow interrogation of the shunt system and collection of CSF for laboratory evaluation, but this should be used only in rare and specific cases. In some cases, accessing the intrathecal space for cisternography using dye studies allows for accurate identification of a site of flow obstruction.

### MANAGEMENT

Management decisions for hydrocephalus are made in light of its natural history, in which the upfront untreated mortality is about 50% and the chance of reaching adulthood is about 20%, with most deaths occurring before 18 months of age. Mortality has decreased to 15% since the advent of shunting in the second half of the 20th century.

Some untreated patients probably survive because of slow evolution or arrest of their hydrocephalus and have variable disability, ranging from mild visual disturbance and gait abnormalities to blindness, bed confinement, and a requirement for total nursing assistance. Without treatment, about 40% of those few survivors have normal intellect. Despite the vast improvement in survival with treatment, only about 50% of those patients have normal intellect and a similar percentage are free of severe behavioral disorders. In patients with cognitive deficits, there is no proven relationship between intellectual ability and head circumference or cortical thickness.

### Treatment Approach

Emergency management of the patient *in extremis* from acute hydrocephalus requires airway protection and immediate CSF diversion prior to further evaluation. This is a treatment algorithm distinct from that required for patients with the subacute or chronic presentation. Medical management of childhood hydrocephalus with agents such as acetazolamide, furosemide, or steroids is mostly ineffective and usually only used as a temporizing measure in mild cases.

The first step in surgical evaluation is to determine whether an obstruction to flow exists, such as a posterior fossa tumor, arachnoid cyst, or aqueductal stenosis, whose removal or bypass would allow for reestablishment of normal CSF circulation. Tumors are resected and cysts may be fenestrated to accomplish this goal. In the case of aqueductal stenosis, perforation of cisternal barriers (eg, third ventriculostomy), may be performed to restore continuity of flow from the ventricles to the subarachnoid space. Shunting of multiple compartments may be performed in more complex cases, such as multiloculated hydrocephalus, or Dandy-Walker syndrome.

In cases for which there is no obvious obstruction, disorders of CSF circulation may occur from impaired absorption. Persistent hydrocephalus occurs after resection of obstructive posterior fossa tumors in approximately one-third of cases, requiring placement of a shunt even after normal CSF corridors seem to be reestablished. In cases of ventricular dilatation after intraventricular hemorrhage of prematurity, small infants may be unable to tolerate placement of a ventriculoperitoneal shunt, so CSF diversion is often accomplished in these cases with serial lumbar or ventricular taps, external ventricular drains, ventriculostomy, or subcutaneous ventricular access devices, depending on the institutional experience. Ventricular size may stabilize after several weeks of these temporizing measures, so ventriculoperitoneal shunt placement is deferred until hydrocephalus is shown to persist after the infant weighs at least 2,000 g because of an improved risk-benefit ratio with surgery.

Hydrocephalus in the setting of active bacterial CNS infection is managed with medical treatment and temporary CSF diversion with serial ventricular or lumbar taps, or ventriculostomy for continuous external CSF drainage. Permanent CSF diversion is used for persistent hydrocephalus after an infection is cleared. Multiloculated (complex) hydrocephalus is often related to previous infection, and poses a difficult surgical problem for which multiple catheter placements and endoscopic procedures may be required.

Experts from areas endemic for tuberculosis state that hydrocephalus of tubercular origin is among the most dreaded and difficult types to manage. The disease process involves thick gelatinous exudates within the basal cisterns and tenacious arachnoid scarring that complicate surgical and, in particular, endoscopic treatments. In some centers, medical management of this form of hydrocephalus may be beneficial for clearance of exudate from the basal cisterns in very select cases under strict treatment protocols. A similarly difficult infection that is increasingly seen among

immigrants to the United States is neurocysticercosis, which results in hydrocephalus in 15% to 30% of patients with neurologic symptoms.

### Specific Treatments

#### Cerebrospinal Fluid Shunting

Permanent diversion of CSF from the ventricle to an extracranial absorptive cavity is through a silastic catheter attached to a 1-way valve and pump/reservoir, which may be accessed with a subcutaneous needle for diagnostic procedures. Valves are selected based on the anticipated intracranial pressure of patients, or have magnetically programmable versions than can be adjusted for changing needs. Common shunt types drain into the peritoneum, pleura, or atrium. Flow-control devices may be included in these systems to reduce siphoning effects that occur when the patient is in the upright position.

#### Endoscopic Third Ventriculostomy

Perforation of the floor of the third ventricle and arachnoid membranes of the basal cistern may be accomplished with an endoscope introduced through a frontal burr hole into the ventricular system. This procedure is ideal for aqueductal stenosis, cases in which shunting is problematic because of repeated infections or failures, and hydrocephalus related to pineal region tumors that can be endoscopically biopsied in conjunction with the procedure. The procedure has a higher likelihood of success in older patients with aqueductal stenosis, compared with infants with post-hemorrhagic hydrocephalus.

### ONGOING CARE

#### Follow-up

Children are usually examined 2 to 4 weeks after surgery, then every 3 months for the first year, every 6 months in the second year, and then annually or, at some institutions, biannually. Clinical assessments include developmental milestones, head circumference, and symptoms and signs of increased intracranial pressure or CNS infection.

Adult survivors of childhood hydrocephalus require life-long follow-up, and many patients require shunt surgery during adulthood. Less than 4% of patients can be weaned from their shunt. Therefore, a transition from pediatric to adult care should be coordinated for these patients when they reach the appropriate age.

#### Complications

Common complications of shunting are shown in Box 269-1. In patients followed into adulthood, the overall incidence of shunt failure is reportedly more than 80%. Thus, hospital admissions for shunt complications are more common than for initial placements. Complications are more common in children with shunts from prematurity, which have increased risk of slit-ventricle syndrome, loculated hydrocephalus, and infection.

The most common cause of shunt failure is obstruction of the proximal catheter, usually caused by infiltration by choroid plexus. The overall incidence of

**BOX 269-1 Shunt Complications**

- Infection
- Mechanical failure: breaks, kinks, or migration of catheter into ventricle or brain tissue
- Overdrainage—slit ventricles
- Overdrainage—subdural hygroma or chronic subdural hematoma
- Blockage: proximal or distal, total or partial intermittent
- Complications specific to ventriculocardiac shunts:
  - Thrombosis around the distal tube
  - Cor pulmonale
  - Shunt nephritis
  - Septicemia and pyemic abscesses
- Complications specific to ventriculopleural shunts:
  - Hydrothorax: characterized by respiratory distress
  - Pyothorax
- Abdominal complications of ventriculoperitoneal shunts:
  - Bowel perforation: rare with current catheter materials
  - Pseudocyst: sterile or infected and presenting as obstruction or abdominal swelling
  - Ascites: malabsorption of CSF; sterile or infected
  - Hernia: at shunt insertion incisions

CSF, cerebrospinal fluid.

shunt obstruction is about 40% during the first year, and is higher (45%) with posthemorrhagic hydrocephalus.

**Shunt Obstruction**

Prior to surgical exploration, it may be difficult to determine whether the site of obstruction is at the proximal or distal catheter or at the valve, although a depressed reservoir unable to be pumped or tapped may indicate a proximal obstruction. On the other hand, small ventricles may collapse around a functioning catheter, making the reservoir unable to be pumped without having a true obstruction. The ability to pump a reservoir does not rule out an obstruction, since a functional blockage could potentially be overcome by manual pumping. Tapping the shunt is only indicated in rare and specific cases, and most obstructions can be diagnosed correctly by other means. For programmable shunts, a first step should be to interrogate the setting to ensure that it has not been inadvertently changed.

**Overdrainage**

Overdrainage is a common complication that results in headaches from intracranial hypotension, and can lead to subdural hematomas or hygromas, especially with cases of severe cortical thinning. Anti-siphon valves and programmable shunts have been designed to help alleviate this problem, but it remains quite common. With programmable shunts, the first step to alleviate symptoms is to increase resistance in the valve.

**Infection**

Infection is a frequent complication of shunting, and usually involves skin flora, such as *Staphylococcus epidermidis*, *Propionibacterium*, and *Staphylococcus aureus*. Younger age is a risk factor for infection, the overall rate of which is approximately 7% in infants. Treatment requires explantation of the shunt system with temporary external drainage and intravenous antibiotics. Shunts are reinserted following clearance of infection, as documented by negative cultures.

**PROGNOSIS**

In chronic cases, hydrocephalus patients may have a good quality of life punctuated with unexpected failures of therapy, repeated medical evaluations, and surgical procedures. Shunt malfunction is a permanent risk, with most patients requiring reoperations into adulthood. Endoscopic third ventriculostomy is available as an alternative to shunting for some patients, but also carries a risk of delayed rapid deterioration that may be fatal.

The etiology of hydrocephalus and the timing of surgical treatment are among the most important prognostic factors for outcome. As this condition is the result of a heterogeneous collection of sequelae from congenital anatomic aberrations, intraventricular insults, and infectious or neoplastic processes across the entire span of childhood, it is almost impossible to determine its independent long-term effects. Both congenital and acquired causes of hydrocephalus may have deleterious effects apart from hydrocephalus, such as dysgenesis of the corpus callosum, whereas the direct effects of hydrocephalus from any cause may include ependymal destruction, compression and collapse of cerebral vasculature, white matter displacement, and cortical neuronal injury.

Early studies failed to find a relationship between brain cortical thickness and intellectual ability, but the effect of these anatomic features cannot be isolated from the contributions of associated medical comorbidities and exposures to repeated surgical procedures and their complications.

In a single-institution retrospective study of 156 cases in Japan, fetal hydrocephalus associated with arachnoid cyst, atresia of the foramen of Monro, corpus callosum agenesis, or fetal intracranial hemorrhage resulted in relatively good outcomes, whereas cases associated with holoprosencephaly, encephalocele, genetic syndromes, or viral infections led to poor outcomes.

**PREVENTION**

Reduction of modifiable risk factors through prenatal care and campaigns to decrease endemic infections are likely to have some effect on the incidence of congenital hydrocephalus. Efforts are underway by multi-center networks to establish standard procedure protocols to reduce shunt complications.

**WHEN TO REFER**

- Pediatric neurology referral for macrocephaly with loss of developmental milestones, headaches, or progressive cognitive deficits
- Ophthalmology consultation for papilledema or suspected deficit in visual acuity or fields

- Urgent neurosurgical consultation with radiographic evidence of hydrocephalus
- Rapid increase in head circumference, crossing growth chart lines, should prompt age-appropriate brain imaging

### WHEN TO ADMIT

- Symptoms of acute or chronic hydrocephalus (see Table 269-2)
- Suspected shunt malfunction/infection in patients with treated hydrocephalus

hypothyroidism (Hashimoto thyroiditis) before thyroid function is diminished, a hyperfunctioning thyroid nodule, pituitary resistance to thyroxine ( $T_4$ ) that results in excess secretion of thyrotropin, and factitious hyperthyroidism caused by administration of exogenous thyroid hormone. Graves disease occurs most frequently in early adolescence, is rare in infancy, and occurs infrequently in childhood. Affected patients often have a family history of thyroid disorders. The prevalence of Graves disease is 6 to 8 times greater in girls than it is in boys.

Graves disease, similar to Hashimoto thyroiditis, is an autoimmune disorder that occurs in patients who have a genetic predisposition, which is itself linked to certain human leukocyte antigen haplotypes. The disease results from the interaction between environmental influences and genes, some of which are thyroid-specific genetic loci while others are susceptibility or immunoregulatory genes. The hyperfunction of the thyroid gland in those with Graves disease is caused by autoantibodies directed against the receptor for thyrotropin. These antibodies, called thyrotropin receptor antibodies (TRAbs), are characterized by an overall predominant stimulatory effect on thyroid cells leading to excessive production and release of  $T_4$ . Included among the TRAbs are (1) thyroid-stimulating immunoglobulins (TSIs) that mimic thyrotropin in their stimulatory action on the production of  $T_4$ , (2) thyrotropin-binding inhibitory immunoglobulins (TBIs) that prevent thyrotropin from binding at its receptor and do not stimulate thyroid cells, and (3) thyrotropin-blocking antibodies. Other antibodies detected in patients who have Graves disease include thyroid growth-stimulating antibodies, which contribute to goiter formation, and antithyroglobulin and antithyroperoxidase antibodies that also are found in patients with Hashimoto thyroiditis. Graves disease can occur in conjunction with other endocrine autoimmune diseases, such as type 1 diabetes mellitus, hypoparathyroidism, and Addison disease, or with other autoimmune diseases, such as myasthenia gravis, periodic paralysis, and vitiligo.

### DIFFERENTIAL DIAGNOSIS

Rarely, children who have Hashimoto thyroiditis are thyrotoxic and have a high titer of TSI autoantibodies in addition to antithyroid antibodies. This condition has been called hashitoxicosis and may be differentiated from routine Graves disease in that the hyperthyroidism is usually a transient phase before the progression to permanent hypothyroidism. Other causes of hyperthyroxinemia are rare, including generalized resistance to thyroid hormone that is found in association with attention-deficit/hyperactivity disorder, factitious hyperthyroidism from excessive administration of thyroid hormone, thyrotropin-secreting pituitary adenomas, and binding-protein changes characterized by normal free  $T_4$  and thyrotropin levels. Finally, hyperthyroidism caused by autonomous thyroid adenomas is rare and can be seen in association with the McCune-Albright syndrome (precocious puberty, café-au-lait pigmentation, and polyostotic fibrous dysplasia).

## Chapter 270 HYPERTHYROIDISM

Nicholas Jospe, MD

### DEFINITIONS

Hyperthyroidism is the result of excessive activity of the thyroid gland. The clinical manifestation of excessive circulating thyroid hormone is called thyrotoxicosis.

### ETIOLOGY

With a few exceptions, thyrotoxicosis in children is the result of Graves disease. Other causes of thyrotoxicosis include the early phase of autoimmune

**Table 270-1** Clinical Signs and Symptoms of Children Who Have Graves Disease

### Relevant History and Physical Examination

Table 270-1 lists the clinical signs and symptoms of children who have Graves disease. Early nonspecific findings include changes in behavior such as nervousness, sleeplessness, emotional lability, decreased school performance, or deteriorating handwriting; these findings largely reflect hyperactivity of the sympathetic nervous system. Graves disease often remains undiagnosed for a long time because children can continue their normal activities without complaints that are overtly suggestive of hyperthyroidism. More prominent cardiovascular signs include tachycardia, a widened pulse pressure, and an overactive precordium. Neuromuscular signs and symptoms include tremor, a shortened deep-tendon reflex relaxation phase, fatigability, and proximal muscle weakness. Despite an increased appetite, the child loses weight more often than he or she gains weight and has frequent, loose bowel movements. Increased perspiration, warmth, heat intolerance, and smoothness of skin appear later. With long-standing disease, tall stature may accompany advanced skeletal maturation in childhood; curtailment of final height as a result of early closure of the epiphyses does not occur.

The size of the goiter when first examined is variable, and its presence often goes unnoticed. However, the thyroid gland, usually seen as diffusely enlarged, is soft and has a clearly delineated border. Thyroid gland enlargement may be difficult to discern in overweight or obese youngsters. The examination should include palpating for the presence of a thrill and auscultating for the presence of a bruit. Measuring the size of the lobes and the isthmus is essential in monitoring disease course. Eye findings also are variable, although severe ophthalmopathy is far less common in children than in adults and, if present, is more likely to resolve completely. Findings include prominence of the eyes (proptosis or exophthalmos), a conspicuous stare (caused by lid retraction and a widened palpebral fissure [Figure 270-1]), and lag of the upper lid on downward gaze. These eye findings are caused by a combination

of hyperactivity of the sympathetic system and of mucopolysaccharide accumulation and infiltration of the orbital fat and ocular muscle cells. The TRAbs are thought to be the cause of ophthalmopathy, because orbital fibroblasts express thyrotropin receptors. Most affected children can be treated with topical ophthalmic lubrication, but orbital fat decompression may be required in patients who have advanced conditions. The management of severe ophthalmopathy can be either medical or surgical (orbital decompression, eye muscle surgery or lid surgery). Medical management includes high-dose glucocorticoids or orbital radiotherapy, either alone or in combination. In children, mucopolysaccharide accumulation in skin and subcutaneous tissue, as with pretibial myxedema, is uncommon.

### Laboratory Evaluation

The initial assessment should include measuring serum free  $T_4$  because, in patients with binding protein increases, total  $T_4$  may be high, yet free  $T_4$  and thyrotropin are normal, thereby ruling out hyperthyroidism. This circumstance is particularly relevant to women taking oral contraceptives, in whom the estrogen raises the binding protein levels, thus increasing the levels of total  $T_4$ , and of total triiodothyronine ( $T_3$ ), but does not affect free  $T_4$  or thyrotropin concentrations. The diagnosis of Graves disease rests on demonstrating elevated levels of  $T_4$  and depression of thyrotropin levels to below the lower limit of detectability in a third-generation thyrotropin assay. A comparison of the patient's levels and age-appropriate normal values of  $T_4$  must be performed before a diagnosis of hyperthyroidism can be made. Measurement of  $T_3$  may help confirm the diagnosis of  $T_3$  toxicosis, although this assessment is rarely necessary. In thyrotoxicosis, the response of thyrotropin to thyroid-releasing hormone is blunted severely or absent. The thyroid-releasing hormone stimulation test is necessary only when Graves disease is thought to exist but the diagnosis is unclear. In equivocal situations, measuring TRAbs, which are present in 95% of patients

**Figure 270-1** The patient on the right exhibits a widened palpebral fissure and goiter; her twin, on the left, was unaffected at the time of this photograph, although later she also developed Graves disease.

who have Graves disease, may help to confirm the diagnosis. In pregnant patients, high TSI levels are predictive of neonatal Graves disease.

Measuring thyroid gland uptake of radioiodine ( $^{123}\text{I}$ ) or technetium ( $^{99\text{m}}\text{Tc}$ ) is useful only to distinguish painless thyroiditis from Graves disease. Patients who have thyroiditis (hashitoxicosis) have a low uptake; patients who have Graves disease have a high uptake. Generally, this study is not necessary at the time of diagnosis. However, measuring the thyroid gland uptake is required if radioablative therapy is performed.

## MANAGEMENT

### Antithyroid Medications

#### Thioamides

The aim of treatment is to reduce thyroid hormone production and block its effect on tissue peripherally. To this end, methimazole (Tapazole) is usually prescribed first. Propylthiouracil (PTU) should no longer be given first. Historically, both PTU and methimazole have been used to reduce thyroid hormone synthesis by inhibiting the oxidation and organification of iodide into  $\text{T}_3$  and  $\text{T}_4$ . PTU also blocks the peripheral conversion of  $\text{T}_4$  into the more active form  $\text{T}_3$ . In 2008, a task force investigated reports of increased rates of PTU-induced liver failure in children. This task force and subsequent studies found that the risk of PTU-induced liver failure leading to transplantation was 5-fold higher (1:2,000) in children than in adults. Furthermore, the risk of reversible PTU-induced liver injury was as much as 1 in 200. Because PTU-induced liver injury can be sudden in onset, rapidly progressive, and potentially irreversible, screening transaminases is not helpful in managing risk. Accordingly, PTU use is strongly discouraged in the pediatric population, and the current recommendations limit its use as a bridge to definitive therapy in the setting of an allergy to methimazole or in early pregnancy. PTU and methimazole are equally effective in inhibiting thyroid hormone production. The half-life is

3 to 4 hours for PTU and 6 to 13 hours for methimazole. Both drugs cross the placenta, although PTU does so less than methimazole and therefore is the preferred drug during early pregnancy. Both drugs are present in small quantities in human milk, and breastfeeding may be continued. Therapy induces euthyroidism somewhat faster with methimazole than with PTU—within weeks to a few months—depending on the size of the thyroid gland. Starting doses of PTU range from 5 to 10 mg/kg body weight, with a maximum of 300 mg/day, given in 3 to 4 divided doses; the dose of methimazole is approximately 0.3 to 0.5 mg/kg, with a maximum of 15 mg/day, given in 2 to 3 divided doses. Once thyroid hormone secretion is depressed, maintenance doses may be given in 2 to 3 daily doses for PTU and 1 to 2 for methimazole. Some older adolescents may require more than 15 mg/day, especially at the start of therapy.

#### Graves Disease

Optimal long-term therapy for Graves disease continues to be the subject of research and some controversy. At present, the recommendation is to titrate the dose of antithyroid medication to maintain the patient in a euthyroid state. In a setting of rapidly relapsing and remitting Graves disease, some physicians administer antithyroid medication until the patient becomes hypothyroid and thereafter, supplement with thyroid hormone. These varying approaches have no effect on rates of relapse.

Therapy with antithyroid medication is usually maintained for a minimum of 18 to 24 months, during which time monitoring the size of the thyroid gland and the TRAb levels can be useful, because shrinkage of the thyroid gland and decreasing TRAb titers predict a greater likelihood of remission after discontinuation of therapy. Thereafter, treatment with antithyroid medication can be stopped, and 20% to 40% of patients remain in remission. The risk of relapse after treatment for a median period of 2 years is higher in patients with severe hyperthyroidism at diagnosis,

younger children, and nonwhite children. Continued patient monitoring with thyroid function tests every 6 months is indicated to detect any subclinical relapse of Graves disease. With variable consensus, because the rate of sustained remission is lower than the initial rate of remission and because the relative utility of the markers has not been reached, the following features do predict a lower rate of remission: a gland greater than 2.5 times normal for age, age younger than 12 years, nonwhite ethnicity, elevated baseline TRAb titer and free  $T_4$  greater than 4 ng/dL.

### Side Effects

Potential side effects of the thioamides include minor reactions that subside spontaneously. These reactions include a purpuric and papular rash, urticaria, joint pain, stiffness, hair loss, nausea or headaches, and a serious reaction—agranulocytosis. Agranulocytosis is an idiosyncratic reaction that occurs in 1 in 500 to 1 in 1,000 cases, usually within the first 3 months of therapy after either form of antithyroid medication. Agranulocytosis is commonly dose-dependent with methimazole, and occurs rarely at lower doses. White blood cell count monitoring is not useful in anticipating agranulocytosis because its onset is sudden. Patients thus need to be told about the significance of a sore throat, mouth sores, and fever as potentially heralding agranulocytosis. In addition to supportive treatment, such as antibiotic therapy, discontinuation of thioamide therapy is necessary. Agranulocytosis spontaneously reverses, and the resumption of therapy with a different thioamide does not usually cause agranulocytosis to recur. Finally, reactions such as drug fever, nephritis, hepatitis, or lupus-like reactions are rare.

### Adjuvant $\beta$ -Adrenergic Blockade

In addition to antithyroid medication, adjuvant  $\beta$ -adrenergic blockade may be accomplished with propranolol or atenolol to control the sympathetic hyperactivity of severe Graves disease. This form of therapy is necessary but only until the hyperthyroidism resolves. There may be relative or absolute contraindication in patients who have cardiac failure or asthma. Patients at relative risk may better tolerate  $\beta_1$ -selective drugs such as atenolol.

### Iodide

Iodide has a minor short-term role as adjuvant therapy in patients who develop toxicity to either PTU or methimazole or as adjunctive therapy immediately before thyroidectomy and for treatment of severe thyrotoxicosis. In practice, it is seldom used. The recommendation by the American Thyroid Association is for routine use of supersaturated potassium iodide for attainment of the euthyroid state, with some gland shrinkage and reduced vascularity before thyroidectomy. Iodide works by transient inhibitory effect on iodine organification, leading to a fall in  $T_4$  and  $T_3$ .

### Definitive Therapy

If a relapse of Graves disease occurs when antithyroid medication is discontinued, then the therapeutic choices include either resumption of antithyroid medication or definitive therapy consisting of radioactive iodine (RAI)

or surgery. The choice depends on factors that affect the chances of success of each form of therapy, such as adherence, patient preference, and surgical expertise. The choice between radioactive iodine and surgical thyroidectomy is a matter of personal preference for many, but not all, patients. Patients with very large glands ( $>80$  g) are poor candidates for RAI. Likewise, patients with poorly controlled Graves disease ( $T_4 >20$  ug/dl or free  $T_4 >5$  ng/dl) should undergo RAI with caution because of the risk of thyroid storm. Furthermore, some data suggest that Graves ophthalmopathy can be exacerbated by RAI, so it should be used cautiously in affected patients. Patients who are pregnant, breastfeeding, or at high risk for pregnancy should not undergo RAI. Finally, although the use of RAI has been expanded in recent years to treat younger and younger patients and has not been demonstrably associated with the development secondary thyroid neoplasms, the role of RAI in children younger than 5 years (who are at the highest risk of thyroid cancer after external radiation) is still under investigation.

Although surgery resolves the symptoms faster, RAI is easy to administer, safer, and equally efficacious except in patients (as noted above) for whom it cannot be safely recommended. The potential for surgical complications from injury to adjacent structures (recurrent laryngeal nerve damage and hypoparathyroidism) dictates that referral be made to an experienced surgeon. This recommendation is predicated on a lower rate of complications in the hands of experienced thyroid surgeons compared to general pediatric surgeons. Permanent hypothyroidism after surgery is the desired outcome. RAI therapy is being used more extensively in children because fears regarding thyroid carcinoma, leukemia, and radiation and genetic damage after treatment with a radioactive substance have been alleviated. RAI concentrates in the thyroid gland and induces cell death over time. On average, three-quarters of patients are cured of hyperthyroidism after 1 dose of radioiodine, and a small fraction may require a second dose months after the first dose. However, there remains debate regarding risks and benefit of total thyroidectomy versus RAI therapy because data on long-term cancer risks are missing or equivocal. Pregnancy is a contraindication for RAI therapy because the iodine crosses the placenta and destroys the fetal thyroid. Following RAI, short-term follow-up care including thyroid function tests is required to determine when to institute thyroid hormone replacement, and long-term follow-up care is required as with anyone else on this therapy.

On rare occasions in children, because most nodules are asymptomatic, thyroid nodules grow or cause symptoms and require treatment. For these, minimally invasive approaches appear effective and safe, such as ultrasound-guided laser or radiofrequency thermal ablation, or percutaneous ethanol injection. Finally, hyperfunctioning nodules remain best treated with RAI.

## COMPLICATIONS

### Thyrotoxic Crisis

Unfortunately, no consistently reliable factors predict the natural course of Graves disease in a given patient, aside possibly from goiter size and the severity of

disease at onset. The clinical course of Graves disease ranges from progression to overt hypothyroidism on one hand to progression to thyrotoxic crisis on the other. Thyrotoxic crisis is an exceptional but severe complication. This diagnosis rests on finding uncontrolled hyperthyroidism and is characterized by a constellation of findings, including cardiac failure, tachycardia, hyperthermia, and central nervous system abnormalities such as confusion, apathy, or coma. Infection (even relatively minor) and trauma can be precipitating factors. Therapy must be expeditious and aggressive and should include antithyroid medication, iodide (Lugol iodine or potassium iodide),  $\beta$ -blockade, antipyresis, glucocorticoids, and medications to prevent cardiac failure. The initial setting for care should be an intensive care unit, to ensure aggressive control of hyperthermia with ice packs and cooling blankets, and thyroidectomy may be performed after 1 week of iodine, which also reduces the vascularity of the gland and the risk for thyroid storm.

### Neonatal Thyrotoxicosis

Graves disease is rare in neonates, affecting approximately 2% of the offspring of affected mothers, and is caused by the transplacental passage of thyroid-directed immunoglobulins from the mother. Transplacental passage of maternal antibodies may occur, even if the mother no longer has active thyroid disease. In addition, stimulatory and blocking maternal thyroid antibodies may disappear at different rates, making the course of neonatal Graves disease difficult to predict. Thus its onset may be immediate or delayed for weeks, and its duration may be brief or prolonged, lasting up to 6 months. Notably, transient neonatal hypothyroidism may result from the transfer of maternal TBII. Neonatal hypothyroidism may also be caused by suppression of the hypothalamic-pituitary-thyroid axis by placentally transferred maternal  $T_4$  from mothers with hyperthyroidism.

The clinical signs and symptoms of neonatal Graves disease include microcephaly, frontal bossing, tachycardia, hypertension, irritability, failure to thrive, flushing, exophthalmos, and goiter. Vomiting, diarrhea, hepatosplenomegaly, jaundice, and thrombocytopenia can also occur. Cardiac failure and arrhythmias account for a mortality that approaches 25% when the disease is severe and treated inadequately. Long-term complications are severe and include hypothyroidism, premature craniosynostosis, and intellectual deficits. Until the disease resolves spontaneously, usually within 1 to 3 months as the maternal antibodies are degraded, adjunctive therapy may be necessary, including potassium iodide (KI, Lugol iodine). In severely hyperactive neonates, propranolol, 2 mg/kg/day, and digitalis for cardiac failure may be required. Glucocorticoid therapy may also be beneficial.

### WHEN TO REFER

New diagnosis of hyperthyroidism.

### WHEN TO ADMIT

Routine diagnosis and therapy of hyperthyroidism do not require hospitalization. Some severe complications of the disorder or its therapy (ocular, cardiovascular, and infectious) may be managed by appropriate subspecialists and with hospitalization.

### Chapter 271

## HYPOCALCEMIA, HYPERCALCEMIA, AND HYPERCALCIURIA

Edna Mancilla, MD; Michael A. Levine, MD

Calcium is a fundamental component of the skeleton and is critical in many physiologic processes, including membrane excitability, neuronal activation, muscular contraction, hormonal secretion, and coagulation. Ninety-nine percent of the body's calcium is found in the skeleton in the form of hydroxyapatite crystals, which provide an exchangeable pool of calcium that participates in maintaining the concentration of extracellular calcium within a narrow physiologic range. Overall control of calcium homeostasis requires a complex interplay between the skeleton, intestine, and kidneys and the integrated action of 2 hormones, parathyroid hormone (PTH) and vitamin D. PTH is the principal calciotropic hormone and is secreted from parathyroid glands in inverse proportion to the concentration of serum calcium. The presence of specific calcium-sensing receptors (CaSR) on the surface of parathyroid glands allows the parathyroid cell to monitor the extracellular calcium concentration and facilitates rapid changes in the secretion of PTH. Ultraviolet (UV) light converts 7-dehydrocholesterol in the skin to cholecalciferol (vitamin  $D_3$ ). Alternatively, vitamin D as ergocalciferol (vitamin  $D_2$ ) or cholecalciferol is ingested. Vitamin D is transported by proteins to the liver, where it is converted to 25-hydroxyvitamin D. PTH increases serum calcium levels directly via activation of osteoclastic bone resorption, and indirectly by stimulating renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol), which activates intestinal absorption of calcium and osteoclastic bone resorption. When PTH is suppressed because of hypercalcemia, levels of 1,25-dihydroxyvitamin D decline, and thus intestinal calcium absorption declines.

Both calcitriol and PTH stimulate calcium reabsorption in the distal renal tubule. Calcitonin is a minor contributor to regulation of serum calcium levels and can decrease serum calcium by its effects on bone and kidney. Thus, the intestines, kidneys, and bones are the target organs for the calcium-regulating hormones,

**Table 271-1** Representative Normal Values for Age for Serum Total Calcium Concentration

		SERUM TOTAL CALCIUM (MG/DL)	
	AGE	MALE	FEMALE
INFANT	0–7 days	7.6–11.3	7.8–11.2
	8–30 days	8.8–11.6	8.6–11.8
	31–90 days	8.7–11.2	8.2–11
	91–180 days	8.5–11.3	8.0–11.4

and an abnormality in either the target organs or the hormones involved in mineral homeostasis can lead to hypocalcemia, hypercalcemia, or hypercalciuria.

The normal values for serum calcium are age dependent. The normal range is broader in infants than for older children, and the upper limit decreases with age. Representative normal values for different ages are shown in Table 271-1, but these concentrations will vary slightly depending on specific laboratory technique or assay.

Most laboratories report the total serum calcium level; about half the plasma calcium is ionized and freely diffusible, whereas 10% is bound to citrate and phosphate but able to diffuse into cells. This is the biologically active form of plasma calcium. The remaining 40% is plasma protein bound and not diffusible into cells. Accordingly, when levels of serum albumin are not normal, the total serum calcium will not correspond to the actual level of active (free) calcium. To determine the level of active calcium, one should measure the serum concentration of ionized calcium ( $iCa^{2+}$ ) or measure both serum total calcium and albumin. A useful formula for estimation of “corrected” total calcium, based on the level of serum calcium, is: adjusted total Ca = measured total Ca +  $[0.8 \times (4.0 - \text{measured albumin})]$ . Simple correction algorithms can also be found on many Web sites (see Tools for Practice at the end of the chapter).

## HYPOCALCEMIA

### Definition

Hypocalcemia is defined as a serum calcium level below the normal age-specific reference range (Table 271-1).

### Epidemiology and Etiology

There are unique causes of hypocalcemia that occur during the first days of life (Box 271-1); the etiology of hypocalcemia in the neonatal period is discussed in Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn. Box 271-1 and Table 271-2

### BOX 271-1 Early Neonatal Hypocalcemia (Within 96 Hours After Birth)

#### CAUSE

- Prematurity
- Low birth weight
- Asphyxia
- Respiratory distress
- Hypomagnesemia
- Hypermagnesemia
- Transfusions
- Respiratory or metabolic alkalosis
- Maternal diabetes mellitus
- Maternal hyperparathyroidism/hypercalcemia
- Toxemia of pregnancy

show the more frequent causes of early neonatal (up to 96 hours), late neonatal (days 4–10 of life), and childhood hypocalcemia. Early-onset hypocalcemia is typically associated with a difficult labor or delivery or low birth weight caused by intrauterine growth restriction or prematurity. Late neonatal hypocalcemia is more frequently observed in formula-fed babies and is caused by high phosphate intake; maternal vitamin D deficiency can also cause late-onset hypocalcemia. The prevalence of vitamin D insufficiency is increasing throughout the world, and it is important to note that severe vitamin D deficiency can cause hypocalcemia. The typical causes of vitamin D insufficiency include decreased sun exposure, use of sun blockers, and low dietary intake of vitamin D. Newborns of vitamin D-deficient mothers may have congenital rickets and hypocalcemia. Moreover, infants who are exclusively breastfed and who do not receive vitamin D supplements are at particular risk for vitamin D deficiency after 6 months of age. Another cause of hypocalcemia

in young infants is congenital hypoparathyroidism. Hypoparathyroidism may be the result of genetic defects in genes involved in parathyroid gland formation, such as loss of *TBX1* as occurs in DiGeorge sequence or *GCM2* as occurs in isolated hypoparathyroidism. By contrast, mutations in the *PTH* gene or the *CASR* gene impair synthesis or secretion of PTH, respectively. In the older child, hypoparathyroidism is the most common endocrine presentation of autoimmune polyglandular syndrome type 1 (APS1) caused by homozygous mutations in the *AIRE* gene. Pseudohypoparathyroidism (PHP) is an unusual cause of biochemical hypoparathyroidism, but circulating levels of PTH are markedly elevated as a result of renal resistance to PTH. Patients with PHP 1a have mutations on the maternal *GNAS* allele that reduce expression or function of Gs $\alpha$ , the protein that couples

many heptahelical receptors to activation of adenylyl cyclase. *GNAS* is a complex imprinted gene, and patients with PHP 1b have other mutations that cause epigenetic *GNAS* defects that impair expression of the maternal *GNAS* allele. Patients with PHP 1a also have resistance to other hormones and manifest hypothyroidism, growth hormone deficiency, and hypogonadism caused by resistance to thyrotropin, growth hormone-releasing hormone, and gonadotropins, respectively. In addition, patients with PHP 1a also manifest a constellation of skeletal defects that are collectively termed Albright hereditary osteodystrophy and that include short stature, brachydactyly, and ectopic ossification.

Hyperphosphatemia can induce hypocalcemia and may occur in children of any age. Hyperphosphatemia can result from excessive intake of phosphate in the form of laxatives or enemas, or secondary to renal

**Figure 271-1** Diagnostic algorithm for hypocalcemia.

failure or tumor lysis syndrome. Lastly, disorders of magnesium homeostasis are common causes of hypocalcemia; hypomagnesemia impairs renal responsiveness to PTH, whereas hypermagnesemia reduces parathyroid secretion of PTH.

### Diagnosis

#### Signs and Symptoms

Hypocalcemia leads to increased neuromuscular excitability causing hyperreflexia, jitteriness, apnea, paresthesias, laryngospasm, and tetany. The older child with hypocalcemia will have a positive Chvostek or Trousseau sign. Central nervous symptoms include irritability, localized or generalized seizures, fatigue, depression, and coma. Cardiac conduction defects may also be observed.

#### Laboratory Findings

Laboratory evaluation should include measurement of serum total and ionized calcium, phosphorus, magnesium, PTH, 25-hydroxyvitamin D; a spot urine calcium and creatinine can be helpful because the calcium-to-creatinine (Ca/Cr) ratio should be very low in patients with hypocalcemia. The vitamin D metabolite that best reflects the body's vitamin D status is 25-hydroxyvitamin D, and thus this metabolite, and not 1,25-dihydroxyvitamin D, should be measured in the initial evaluation. Electrocardiography may show a prolonged QTc interval. Patients with hypoparathyroidism will have low (or inappropriate) normal serum PTH levels, whereas patients with PHP will have

elevated serum levels of PTH. In both conditions, serum phosphorus levels are elevated. By contrast, patients with vitamin D deficiency will have elevated serum PTH levels and hypophosphatemia because proximal renal tubular reabsorption of phosphorus is reduced in response to PTH action.

#### Imaging

Cerebral calcifications may be observed in chronic hypocalcemia when the calcium-phosphate product has been elevated because of hyperphosphatemia. It is recommended to maintain the calcium-phosphate product less than  $55 \text{ mg}^2/\text{dL}^2$  for several years. This occurs most commonly in patients with hypoparathyroidism, PHP, and chronic renal insufficiency.

Long bone radiographs may show demineralization and rachitic changes, such as cupping and fraying of the metaphysis, when hypocalcemia is associated with hypophosphatemia. This occurs most commonly in patients with vitamin D deficiency or resistance, in whom secondary (adaptive) hyperparathyroidism leads to reduced tubular resorption of phosphorus.

#### Diagnostic Approach

A reasonable diagnostic approach is summarized in the algorithm in Figure 271-1.

### Management

#### Neonatal Hypocalcemia

Early-onset hypocalcemia may require treatment with oral calcium supplementation (40–80 mg/kg per day in

divided doses) for several days; in cases of symptomatic hypocalcemia, intravenous infusion of calcium may be required. Neonates with late-onset hypocalcemia will require supplementation of infant formula with elemental calcium to achieve a 4:1 ratio of calcium to phosphorus; vitamin D or calcitriol may also be necessary.

### Outpatient Management

Optimal treatment of hypocalcemia requires both vitamin D and oral calcium supplementation. A typical regimen is 20 to 50 mg per kg of elemental calcium daily in divided doses; calcium should best be taken with meals when the serum phosphorus level is elevated. Various calcium salts are available and differ in the amount of elemental calcium per gram of salt: calcium carbonate (40% calcium), calcium citrate (21% calcium), or calcium gluconate (9% calcium). In cases of concomitant antacid medication, calcium citrate is preferred. Magnesium supplements should be used when serum magnesium is low. Vitamin D deficiency is treated with vitamin D in the form of cholecalciferol (vitamin D<sub>3</sub>) or ergocalciferol (vitamin D<sub>2</sub>), 1,000 to 4,000 units per day, with careful monitoring to ensure adequate replacement and to avoid toxicity.

Patients with chronic hypocalcemia, as in hypoparathyroidism, PHP, or vitamin D-dependent rickets, should be treated with calcium supplements plus calcitriol (50–90 ng/kg/day in 2 divided doses). Calcitriol has a much shorter half-life than other forms of vitamin D and does not require PTH action for full biologic effect.

### Admission to Hospital

Patients with acute and symptomatic hypocalcemia require hospital admission and treatment with intravenous calcium. Injections of calcium salts are recommended only in acute cardiac emergencies. In all other cases of symptomatic hypocalcemia, a continuous infusion of calcium, at a rate of 1 to 3 mg/kg per hour of elemental calcium (such as 10% calcium gluconate) will safely normalize serum calcium levels and maintain constant concentrations better than repeated bolus infusions. Once the serum calcium level has been normalized, the patient can be transitioned to oral therapy with calcium and vitamin D.

### Ongoing Care

Regular follow-up by an endocrinologist is indicated in chronic hypocalcemia. Calcium supplements and vitamin D treatment should be adjusted to maintain calcium levels in the low-normal range to avoid hypercalciuria.

### Complications

Nephrocalcinosis and nephrolithiasis are rare complications of hypercalcemia and hypercalciuria. Thus, both serum and urine calcium concentrations should be regularly monitored. Spot urine collections may be used to determine urinary calcium and creatinine concentrations for screening Ca/Cr ratios (normal values detailed below in the section on hypercalciuria).

### Prevention

Calcium and vitamin D deficiency should be prevented by an adequate diet and sun exposure. The current recommended daily intake for vitamin D is 400 IU for infants, children, and adolescents, but some children may require higher doses to maintain normal serum levels of 25-hydroxyvitamin D (>30 ng/mL). All breast-fed infants will need to be supplemented with 400 IU of vitamin D per day. The recommended calcium intake by age in the United States increases from 210 mg/day at 0 to 6 months of age to 1,300 mg/day at 9 to 18 years.

## HYPERCALCEMIA

### Definition

Hypercalcemia is defined as a serum calcium level above the normal age specific range (Table 271-1).

### Epidemiology and Etiology

In children and adolescents, the most common causes of hypercalcemia are increased PTH secretion, increased vitamin D ingestion or activation, decreased serum phosphate levels, or increased bone resorption from immobilization, cancer, or hyperthyroidism. Osteoclastic bone resorption is increased in nearly all cases of hypercalcemia. The causes of hypercalcemia may be categorized by age. In particular, hypercalcemia in the neonatal period may be related to maternal disorders of mineral metabolism, which are described in Chapter 100, Respiratory Distress and Breathing Disorders in the Newborn. When hypercalcemia occurs within the first few weeks of life, the cause is usually hyperparathyroidism owing to prior gestational hypocalcemia or familial hypocalciuric hypercalcemia (FHH), subcutaneous fat necrosis, or Williams syndrome. Some newborns may present with life-threatening hypercalcemia and marked skeletal demineralization, a variant of FHH that has been termed *severe neonatal hyperparathyroidism* (NSHPT). In older children, hypercalcemia is most commonly caused by primary hyperparathyroidism, immobilization, malignancy, and granulomatous disease (Table 271-2). A comprehensive listing of the causes of hypercalcemia in these 2 age groups is presented in Table 271-3 and Table 271-4.

### Diagnosis

#### Signs and Symptoms

The signs and symptoms of hypercalcemia will reflect the acuity and degree of hypercalcemia as well as the patient's age. Moderate to severe hypercalcemia affects the nervous system, leading to weakness, hypotonia, lethargy, and seizures. Significant polyuria leading to dehydration is produced by stimulation of the CaSR in the renal collecting ducts. When hypercalciuria is severe, nephrocalcinosis, nephrolithiasis, and hematuria may be initial manifestations of hypercalcemia. Gastrointestinal complaints such as anorexia, nausea, vomiting, and abdominal pain may be observed and are often accompanied by failure to thrive. Cardiovascular signs include hypertension and abnormalities in cardiac conduction. In neonates and infants, symptoms are nonspecific and hypercalcemia may be detected in the workup for failure to thrive.

### Laboratory Findings

Laboratory evaluation should include measurement of serum total and ionized calcium, phosphorus, magnesium, PTH, 25-hydroxyvitamin D, and calcitriol, as well as urinary calcium and creatinine. Hypercalcemia with hypophosphatemia is observed in hyperparathyroidism,

and an inappropriately elevated PTH level for the calcium level will confirm this diagnosis. Children with FHH or NSPHT will have very low urinary calcium levels with fractional calcium excretion (FeCa) that is less than 1%. Hypercalcemia with a low PTH level may be caused by increased vitamin D intake (elevated

**Figure 271-2** Diagnostic algorithm for hypercalcemia.

serum 25-hydroxyvitamin D) or activation (elevated serum calcitriol) or malignancy (often with increased PTHrP levels). Immobilization and calcium gluttomy are associated with low serum levels of PTH and vitamin D metabolites but markedly increased urinary calcium excretion.

### Imaging

Imaging studies should be reserved for confirmation of a biochemical diagnosis. Technetium-99m sestamibi scanning and neck ultrasound can identify a solitary parathyroid adenoma in 60% to 90% of patients with primary hyperparathyroidism. End-organ damage is assessed by renal ultrasound and radiographs. Renal ultrasound may reveal the presence of nephrocalcinosis or nephrolithiasis. Skeletal radiographs may disclose demineralization or subperiosteal resorption in some cases of primary hyperparathyroidism, but dual-energy x-ray absorptiometry (DXA) is a far more sensitive procedure that can demonstrate reduced bone density in most patients with longstanding hypercalcemia.

### Diagnostic Approach

A suggested diagnostic approach is found in the algorithm in Figure 271-2.

### Management

#### Outpatient Referral

Children with mild asymptomatic hypercalcemia should be referred for outpatient evaluation. The need for treatment depends on the degree of hypercalcemia and the presence or absence of clinical symptoms. If calcium levels are lower than 12 mg/dL and the patient has no symptoms, it is usually unnecessary to treat the hypercalcemia. Children with mild hypercalcemia, Williams syndrome, or vitamin D excess may require nothing more than a low-calcium, low-vitamin D diet. Patients with asymptomatic hypercalcemia caused by FHH require no intervention.

#### Admission to Hospital

Patients with moderate calcium elevations (12–14 mg/dL) and symptoms consistent with hypercalcemia should be admitted to the hospital. Patients without symptoms may require only adequate hydration. Patients with calcium levels higher than 14 mg/dL should be treated aggressively, regardless of symptoms. The main goals of treatment are to increase urinary calcium excretion and decrease bone resorption. Aggressive hydration with normal saline is the initial treatment with the aim of inducing a natriuresis

that will enhance urinary calcium excretion. Volume expansion using intravenous saline infusion will result in a marked increase in sodium, calcium, and water delivery to the loop of Henle, with consequent marked increase in urinary excretion of calcium as well as sodium, potassium, chloride, magnesium, and water. It is important to replace water, sodium, potassium, and chloride continuously and, if this regimen exceeds 10 hours, to replace magnesium. In older adolescents, the urinary flow should exceed 250 mL/hr during this time, and the serum calcium level will start decreasing within 2 to 4 hours and approach the normal range in 12 to 24 hours. In most patients, the intravenous infusion of saline will effect a satisfactory diuresis; potent loop diuretics are rarely necessary and should be avoided or used with extreme caution because these agents may paradoxically worsen hypercalcemia by inducing dehydration and decreasing the glomerular filtration rate. Parenteral calcitonin and intravenous bisphosphonates decrease osteoclastic activity and are generally effective in hypercalcemic patients with increased bone resorption regardless of the etiology. Calcitonin can be given subcutaneously or intramuscularly every 12 hours (4 IU/kg). Its action is rapid (4–6 hours), and the calcium level is usually lowered by 1 to 2 mg/dL. However, calcitonin is effective in only 60% to 70% of patients, and most of them develop tachyphylaxis in 48 to 72 hours. Intravenous bisphosphonates can lower the serum calcium level with a maximal effect in 2 to 4 days. The duration of effect is 1 to 4 weeks and varies according to the underlying cause of hypercalcemia and the specific bisphosphonate. Pamidronate and zoledronate are the most effective bisphosphonates for treatment of hypercalcemia. Zoledronate is the most potent bisphosphonate and has the longest lasting effect; it is given in a 30-minute IV infusion (up to 4 mg). Pamidronate is given by IV infusion over 4 to 24 hours. The initial dose varies, and in children with normal renal function, a typical dose consists of 1 to 2 mg/kg, up to 30 mg if the calcium level is lower than 12 mg/dL, 60 mg if the calcium level is 12 to 13.5 mg/dL, and 90 mg if the calcium level is above that level. A subsequent dose of an intravenous bisphosphonate can be given after 7 days. Because it may take several days for bisphosphonates to reduce the serum calcium level, these agents should be used in combination with rapid-acting therapies such as IV saline infusion and calcitonin injections. Initial treatment is followed by etiology-specific treatment (eg, cinacalcet or surgery in primary hyperparathyroidism; corticosteroids or ketoconazole, chloroquine, and hydroxychloroquine to inhibit calcitriol production in cases of lymphoma or granulomatous disease).

### Ongoing Care

Follow-up will depend on the etiology. Hyperparathyroidism caused by adenomas in children is most often from a single adenoma and is cured by surgery. Other causes may require chronic follow-up to prevent complications.

### Complications

Bone disease secondary to increased resorption in hyperparathyroidism should be prevented by timely

**Table 271-5** Spot Urine Ca/Cr Ratio

AGE	CA/CR RATIO
<7 months	0.07–0.86
7–18 months	0.07–0.6
18 months–6 years	0.03–0.42
Adult	0.05–0.22

resection. Renal disease secondary to hypercalcemia should be prevented or ameliorated by adequate management of the hypercalcemia.

### Prevention

Acute hypercalcemia and end-organ damage are prevented by etiology-specific and prompt symptomatic treatment.

## HYPERCALCIURIA

### Definition

Hypercalciuria is defined as excessive renal excretion of calcium, measured as a urinary calcium excretion of more than 4 mg/kg/day and/or an elevated Ca/Cr ratio for age, in either a spot or timed urine collection (Table 271-5).

### Epidemiology and Etiology

Hypercalciuria occurs in 3% to 6% of children and is most often idiopathic. Causes of hypercalciuria are listed in Table 271-6, including primary and secondary renal tubular disorders, drugs such as the carbonic anhydrase inhibitors, chronic acidosis caused by dietary factors such as a ketogenic diet, increased gastrointestinal absorption of calcium, and increased osteoclastic bone resorption. Hypercalciuria is a risk factor for nephrolithiasis, nephrocalcinosis, and low bone density. The relative risk for stone production seems to be a continuous function of urinary calcium excretion rather than a threshold effect, such that a single arbitrary level cannot distinguish healthy people from those who form stones. Although the total 24-hour urinary calcium excretion remains a useful measure, it is likely that the urinary calcium concentration is a more reliable predictor of stone formation risk.

The most common types of clinically significant hypercalciuria are absorptive, renal leak, resorptive, and renal phosphate leak. Although the genes involved in many forms of hypercalciuria are now known, the genetic basis for hypercalciuria in most patients remains unknown. The most common cause of hypercalciuria is absorptive hypercalciuria, which is characterized by an increase in the gastrointestinal absorption of calcium. This produces a mild increase in serum calcium levels that depresses PTH secretion. Typically, serum PTH is in the low-normal range. Serum levels of 1,25-dihydroxyvitamin D are elevated in about half of affected patients. Absorptive hypercalciuria can be classified into 3 types. Type I is relatively uncommon

**Table 271-6** Causes of Hypercalciuria

Topiramate, Zonisamide		

and is the most severe type of absorptive hypercalciuria. Urinary calcium excretion is relatively unresponsive to dietary modifications, including severe dietary calcium restriction, but can normalize during periods of fasting. Type II absorptive hypercalciuria is the most common form and is responsive to moderate dietary calcium restriction. Type III absorptive hypercalciuria is related to a renal phosphate leak and is also relatively uncommon. Renal hyperphosphaturia is related to a defect in expression or function of sodium-phosphate cotransporters and causes mild hypophosphatemia. The low serum phosphate suppresses serum levels of FGF23, a phosphatonin that decreases expression of sodium-phosphate cotransporters and activity of the CYP27B enzyme that catalyzes 1 $\alpha$ -hydroxylation of 25-hydroxyvitamin D. Thus, suppression of FGF23 increases the synthesis of 1,25-dihydroxyvitamin D and thereby increases intestinal absorption of both phosphate and calcium. The unnecessary calcium absorbed is ultimately excreted in the urine, causing the hypercalciuria.

Renal leak hypercalciuria is far less common than absorptive hypercalciuria and is caused by defects in the kidneys that impair renal calcium resorption. The primary renal loss of calcium leads to mild hypocalcemia and secondary hyperparathyroidism, which is useful in diagnosing this condition.

Resorptive hypercalciuria is the result of increased osteoclastic bone resorption. Calcium and phosphorus are released from the skeleton in response to unknown factors, which suppresses serum levels of PTH and 1,25-dihydroxyvitamin D. The low serum levels of PTH and 1,25-dihydroxyvitamin D inhibit renal calcium reabsorption, and in the face of an increased filtered load of calcium, significant hypercalciuria ensues.

## Diagnosis

### Signs and Symptoms

Hypercalciuria may present with symptoms such as dysuria or abdominal or flank pain; there may

be nephrolithiasis, recurrent urinary tract infections, or osteoporosis. Physical examination may reveal growth restriction as a manifestation of renal tubular acidosis. Symptoms of hypercalcemia may be predominant when hypercalciuria is secondary to one of the hypercalcemic disorders listed in the previous section.

### Laboratory Evaluation

Evaluation of urinary calcium excretion preferably includes a 24-hour urine collection for calcium, creatinine, sodium, potassium, citrate, and oxalate. Serum calcium should be measured, and if elevated, a comprehensive evaluation of hypercalcemia should follow, as detailed in the section above.

### Imaging

Renal ultrasound may show nephrolithiasis or nephrocalcinosis. Computed tomography scan or intravenous pyelogram may be necessary to clarify a questionable obstruction or stones.

## Management

### Outpatient Referral

Patients with an active renal stone or a past history of renal stone should be referred for evaluation by a specialist. Management will depend on the pathophysiology as described previously. Symptomatic hypercalciuria should be treated with dietary measures and pharmacotherapy. Dietary management consists of increasing fluid intake and reducing the daily intake of sodium. Sodium intake should not exceed the recommended daily allowance of 1.2 g/day for 4- to 8-year-olds and 1.5 g/day for 9- to 18-year-olds. Calcium intake should be maintained at recommended values for age to avoid bone demineralization. Primary pharmacologic therapy focuses on reducing urinary excretion of calcium and includes thiazides, orthophosphates, and potassium citrate. Other therapies are more directed at reducing intestinal absorption

of calcium through the use of sodium cellulose phosphate and increased fiber. Dipyridamole has been used with limited success to increase the renal tubular reabsorption of phosphorus and reduce synthesis of 1,25-dihydroxyvitamin D, and is a particularly attractive option in patients with a renal phosphorus leak. Patients with increased osteoclastic bone resorption, so-called resorptive hypercalciuria, may benefit from use of bisphosphonates, such as oral alendronate or intravenous pamidronate or zoledronic acid, which increase bone deposition of calcium, thus removing it from the circulation before it can be excreted. This improves bone density and helps reduce urinary calcium levels. The main benefit may be in protecting the bones from calcium depletion and demineralization in hypercalciuric patients.

Potassium citrate prevents nephrolithiasis and is especially useful in patients with renal tubular acidosis. It has also been suggested to prevent lithiasis in patients with a ketogenic diet. In many instances, several drugs will be required to effectively reduce excessive urinary calcium excretion. Ultimately, the success of these therapeutic interventions will be limited by several factors that together reduce adherence over time. First, patients are often disappointed by the development of medication side effects, which range from hypokalemia and hypomagnesemia from thiazides to diarrhea and gastrointestinal distress from phosphate salts. Second, patients often become discouraged by the necessity for lifelong treatment. And lastly, in the absence of clinically active stone disease, patients are usually asymptomatic despite significant hypercalciuria and thus do not perceive any benefit from long-term treatment.

### Admission to Hospital

Hypercalciuria per se will not require hospitalization unless there is obstructive stone disease or infection.

### Ongoing Care

Follow-up is scheduled at regular intervals to monitor therapy and complications.

### Complications

Complications include renal infection or insufficiency secondary to untreated lithiasis.

### Prevention

Nutritional and medical treatment should be maintained in symptomatic patients to prevent recurrent lithiasis.

## SUMMARY

In summary, a few basic laboratory tests, including serum calcium, phosphorus, alkaline phosphatase, 25-hydroxyvitamin D and PTH, and urine studies, will direct the physician toward an effective diagnosis of patients with hypercalcemia, hypocalcemia, or hypercalciuria. Further testing and imaging studies may be needed depending on the initial findings and are usually deferred to the specialist. We have increasing knowledge of the molecular etiology of many genetic disorders of mineral metabolism, and these gene tests may be of value in confirming the diagnosis and providing the basis for genetic counseling.

## Chapter 272

# HYPOSPADIAS, EPISPADIAS, AND CRYPTORCHIDISM

Brian Inouye, MD; Ali Tourchi, MD; John P. Gearhart, MD

Abnormal neonatal genitalia worry parents. While male hypospadias, epispadias, and cryptorchidism are readily accessible for observation, and thus cause more parental preoccupation, female hypospadias and epispadias are also problematic. While cosmesis and sexual function are the initial concerns, genitourinary complications may arise and warrant pediatric urologic consultation.

## GENITAL ABNORMALITY

An external genital deformity in the infant boy is usually obvious. Penile size is one cause of parental distress that is not often noted at birth but perhaps

several weeks later as the baby gains weight. A retracted penis may seem to disappear despite being 4 cm long in a suprapubic pad of fat. The parents should be assured kindly that the condition will correct itself in time. Only rarely does a real problem exist, namely a micropenis, in which the penis has a stretched length of less than 2 standard deviations below the mean or is less than 2.5 cm in length, which suggests a dysmorphic abnormality. Circumcision should be delayed in infants who have micropenis and should not be performed until a thorough evaluation has been performed by a pediatric endocrinologist and a pediatric urologist.

### Hypospadias

Hypospadias is one of the most frequent genital problems, occurring approximately in 1 out of 200 male births, with recent studies suggesting an increasing incidence. This anomaly consists of maldevelopment of the ventral aspect of the penis, urethra, corpora spongiosum and cavernosa, and ventral prepuce. It also commonly presents with chordee and penile hypoplasia.

The exact mechanism remains unknown; however, it is most likely multifactorial. Endocrine disruptors, such as maternal use of progestins and in vitro fertilization, seem to increase the risk of hypospadias. Furthermore, over the past 3 decades, the incidence of hypospadias has increased with the use of environmental chemicals such as polychlorinated biphenyls and polyhalogenated hydrocarbons and phthalates.

This anomaly is a continuum, with approximately 70% of cases having an aberrant meatus at the glans penis, subcoronal margin, or on the corona. The remaining hypospadias cases are characterized by a more proximal meatus located at the mid-shaft, scrotal or perineal region (Figure 272-1). Classification used to be determined by the location of the urethral meatus before repair. However, recent classification schema additionally consider the location of the meatus after chordee correction, the glans (cleft, incomplete cleft or flat), the quality and width of the urethra, the prepuce (incomplete or complete), and the degree of the penile curvature and presence of scrotal transposition. This system classifies hypospadias as either anterior, middle, or posterior. Anterior hypospadias, which occurs in 65% of cases, has been further categorized as glanular or subcoronal. Middle hypospadias, which is seen in 15% of cases, is further delineated into distal penile, midshaft, or proximal penile classifications. Posterior hypospadias, occurring in 20% of cases, can be further described as penoscrotal, scrotal, or perineal. Description of the glans can be separated into 3 categories: cleft glans with deep groove and proper clefting, incomplete cleft glans with split glans and shallow groove, or flat glans with no groove and short-ending urethral plate at the glans. Although different categorizations have been proposed to describe hypospadias, it is thought that the severity of hypospadias is still best judged at the time of surgery.

All patients should undergo a complete history and physical examination. Pediatricians should attempt to classify the hypospadias during the examination, making note of chordee, meatal stenosis, penoscrotal

transposition, and penile torsion. Feeling a bulge or dribbling of urine may indicate a diverticulum.

In approximately 10% of cases, an associated unilateral or bilateral cryptorchidism is present. About 25% of these patients have an intersex anomaly requiring consultation from a pediatric endocrinologist and geneticist to evaluate genetic gender and endocrinological abnormalities. Severity of hypospadias is also significantly correlated with intersex disorders requiring the same referral and workup.

Voiding cystourethrography or retrograde urethrography are rarely performed in patients with anterior hypospadias. However, a voiding cystourethrogram should be carried out in the patient with an enlarged prostatic utricle to understand the utricle anatomy and assess possible future problems in regard to urinary stasis, infection, stone formation, and difficulty with catheterization.

Hypospadias requires surgical correction to create a straight penis, approximate the urethral meatus, normalize voiding and erections, and reconstruct a uniform urethra and glans. Many techniques have similar outcomes after repairing the urethra, skin, and ventral chordee. Because sufficient penile tissue is required for hypospadias repair, circumcision should not be performed prior to hypospadias repair.

The 5 steps in hypospadias repair—orthoplasty, urethroplasty, meatoplasty, scrotoplasty, and skin coverage—can be done in a single stage or multiple stages. While microsurgery favored single-stage repairs in the past, recent techniques for mobilizing and transecting the urethral plate while lengthening the corpora have popularized the 2-staged approach. Still, the 2-staged approach is usually reserved for cases that need a corporoeplasty or if there is a paucity of healthy tissue. Because of similar outcomes, the best technique depends on surgeon experience, meatal position, the meatus and glans configuration, presence or absence of chordee, quality of ventral skin coverage, the quality of urethral plate, the availability of foreskin, and the circumcision status.

Timing of hypospadias repair depends on the environment in which the patient will be managed, risk of anesthesia, penile size, and the psychosexual milestones in infancy and early childhood. Previous guidelines recommended hypospadias surgery after 4 years of age to prevent separation anxiety between the patient and parent. Improved surgical and anesthetic techniques have led to surgery being a 1-day, outpatient procedure that minimizes separation anxiety, allowing it to be done earlier in life to minimize potential psychological disruptions caused by genital surgery. As the risk of anesthesia after the age of 6 months does not differ from that in older patients, the American Academy of Pediatrics suggests that the optimal time for hypospadias repair is between 6 and 12 months of age.

Perioperative hormonal therapy is controversial. Five percent testosterone cream or intramuscular injections of testosterone propionate can enhance penile size before the surgery by inducing better penile vascularization and increasing size of the urethral plate. Furthermore, several studies have advised androgen stimulation in patients with a small genital tubercle

**Figure 272-1** Varieties of hypospadias. **A**, Coronal. **B**, Distal shaft. **C**, Penoscrotal. **D**, Perineal.

(<25 mm long) or small gland (diameter <15 mm) during the first year of life.

### Epispadias

Epispadias is a rare entity that occurs in 1 in every 117,000 male births, and only 1 of every 484,000 female births, and is usually described as a part of the exstrophy epispadias complex (EEC). This anomaly represents a spectrum of abdominal and pelvic midline malformations ranging in severity from

epispadias to classic bladder exstrophy and cloacal exstrophy. Complete epispadias (CE) is the least severe form of EEC and presents with a dorsally open urethral meatus with mild pubic diastasis and a closed anterior abdominal wall and bladder. CE can be categorized into glandular, coronal, shaft, or penopubic epispadias. A more proximal deformity may be associated with complete urinary incontinence because of involvement of the bladder neck area along with distortion of the normal architecture of the pubic bones.

In most cases of epispadias, the prepuce is usually absent at the dorsum of the penis and is redundant tissue hanging from the ventral side, leaving the glans uncovered. The gland is broad and spade-like, with a dorsally directed preputial opening and an upward urinary stream. A dorsal chordee or abnormalities of penile raphe can suggest epispadias in difficult diagnostic cases, such as if the prepuce is covering the urethral defect.

Early consultation with the pediatric urologist is necessary and circumcision should be avoided in these patients to avoid reducing tissue. Epispadias repair corrects the dorsal chordee, reconstructs the glans and urethra, and closes the penile skin. Since these patients may also have a pubic diastasis, they may require a pelvic osteotomy for complete repair.

## CRYPTORCHIDISM

The testes are normally descended in a full-term newborn (depending on the birth weight), and may differ in size. Given that the testes descend from within the abdomen to the scrotum by approximately week 36 of fetal life, the incidence of cryptorchidism (undescended testes) is much higher in the premature infant, ranging from 20% to 40% instead of 2.2% to 3.8% in term neonates weighing 2,500 g or more at birth. Besides prematurity and low birth weight, other risk factors for cryptorchidism include breech presentation and maternal diabetes. There is a 10-fold risk of cryptorchidism in twins, and a 3.5-fold increase in brothers.

Seventy-five to 80% of undescended testicles are palpable and right-sided. The testes are nonpalpable in 10% of cryptorchidism cases. Of these nonpalpable cases, 50% of the testes are located in the inguinal canal or abdomen while 50% of the time the testis is absent secondary to fetal torsion and infarct. Even though premature infants have higher rates of cryptorchidism than term infants, they have a higher rate of spontaneous descent (80%–90% vs 50%–70%) that also occurs earlier (by age 1–3 months).

Diagnosis relies on examination. It is recommended to examine testicular position in an infant in the supine, cross-legged, and standing positions to ensure proper classification and overcome an overactive cremasteric reflex. To palpate the testis, the examiner must feel from above downward, *milking* the testis from the inguinal canal into the scrotum. The older patient can help this process by coughing or straining. Cold hands and abrupt palpation can invoke the cremasteric reflex. If one or the other of the testes is not palpable, then the examiner should search beyond the scrotum and the inguinal canal to the femoral triangle and the inner thigh. Many undescended testes are associated with an inguinal hernia and possibly a hydrocele; these masses can make palpation of the testes even more difficult. If the testis is impalpable and a hernia is present, then the testis usually lies just inside the internal inguinal ring. Ultrasound and magnetic resonance imaging may be helpful for inguinal testis location, but have low sensitivities for intraabdominal testes, so surgical exploration is still the diagnostic

standard for diagnosis of nonpalpable testes. Further testing, such as karyotype and hormone analysis, may be warranted if there are additional anomalies, as these may be indications of syndromic cryptorchidism.

If the nonpalpable testis is absent secondary to torsion, there is a high likelihood of perinatal asynchronous torsion of the contralateral testis, which has led some to recommend emergent exploration and orchiopexy. Otherwise, observation is indicated for the first 6 months of life, because spontaneous descent is unlikely after a year, testicular growth is more likely after early orchiopexy, and orchiopexy may be aided by the early hormonal surge at this time. Continued observation is required in cases of successful descent to monitor for recurrent cryptorchidism. Even if the testis is normal at birth, acquired cryptorchidism, where it spontaneously ascends, may occur. This accounts for 2% to 20% of all orchiopexies.

Cryptorchidism has been associated with infertility and malignancy. While sperm and sex hormone levels are decreased in men with a unilateral undescended testis, paternity data is similar to that of normal men. However, bilateral cryptorchid men have significantly lower fertility potential compared to a normal man. Early orchiopexy may aid fertility, as there are more Sertoli and germ cells in testes that undergo orchiopexy at 9 months versus 3 years. There is a 2.5- to 8-fold increase in overall risk for malignant transformation of all undescended testes. Undergoing a prepubertal orchiopexy confers a 2- to 3-fold increase in risk of malignancy in the testis, while an orchiopexy at age 10 to 13 years of age increases the risk another 2- to 6-fold. Controversy exists over whether the noncryptorchid contralateral testis is at increased risk of malignancy.

Surgery is indicated if the testis is not down by 12 months of age. Surgery is currently done on an ambulatory basis with either open orchiopexy for palpable testes or laparoscopic exploration and subsequent orchiopexy for nonpalpable testes. There is no difference in outcomes between open and laparoscopic techniques for nonpalpable testes. If there is a ipsilateral hernia, with or without hydrocele, then herniorrhaphy should be done to decrease the risk of incarceration postoperatively. Seventy-five percent of cryptorchid patients have a correct postoperative testicular position. Still, periodic examinations are important for any abnormalities. An orchiectomy with a prosthesis placement may be done if the testis is abnormal.

If the parents refuse or are reluctant to allow surgery, human chorionic gonadotropin (hCG) at 1,500 IU/m<sup>2</sup> body surface area has been given intramuscularly twice a week for 4 weeks. hCG has been seen to lead to testicular descent, but these rates are only 10% greater than placebo. Complications are mild with this dosage, but include possible re-ascent, so monitoring is required. Still, controversy exists over whether hCG is truly useful as adjunct therapy for true cryptorchidism, in determining retractile versus true cryptorchidism, and in stimulating germ cells. If the testis remains undescended or retracts, surgery must be done.

**WHEN TO REFER**

- All cases of hypospadias to pediatric urology.
- All cases of epispadias to pediatric urology.
- Undescended testis in a 1-year-old to pediatric urology.
- Cryptorchidism whose parents want to avoid surgery to pediatric endocrinology for hormonal treatment.
- Genital abnormalities that present with hypospadias and cryptorchidism to pediatric endocrinology.

**WHEN TO ADMIT**

- All procedures can be done at an ambulatory, same-day surgery center.

**Chapter 273****HYPOTHYROIDISM**

Craig C. Orlowski, MD

**INTRODUCTION**

Few diseases affect multiple systems so severely yet are associated with so many subtle symptoms and signs as hypothyroidism. The clinical manifestations of congenital hypothyroidism differ markedly from those of acquired disease in children and adolescents; for this reason, the primary care physician must distinguish between congenital and juvenile-acquired hypothyroidism. Congenital and acquired hypothyroidism may be either familial or sporadic, may occur with or without enlargement of the thyroid gland (goiter, thyromegaly), and may be transient, or progress to a more permanent disorder.

**DEFINITION**

Hypothyroidism is the underproduction of thyroid hormones. This deficiency may result in a range of signs and symptoms from mild to severe. Primary hypothyroidism is insufficient thyroid hormone production caused by a failure of the thyroid gland. Secondary and tertiary hypothyroidism result from the insufficient production of *thyrotropin* from either pituitary or hypothalamic abnormalities, respectively.

**ETIOLOGY**

The causes of congenital and juvenile hypothyroidism usually differ (see Box 273-1). In most cases of permanent congenital hypothyroidism, the underlying mechanism of the condition is unknown. Approximately 85% of patients with congenital hypothyroidism have no thyroid tissue (athyreosis), an ectopic thyroid gland, or a hypoplastic thyroid gland found in the normal anterior cervical location. Mutations in genes currently known to be involved in thyroid genesis explain only a small portion of cases of congenital hypothyroidism. Several inborn errors of thyroid hormone synthesis are inherited as autosomal-recessive traits and usually cause thyromegaly noted on physical examination. Several types of transient hypothyroidism can occur. In 2% of cases, antibodies that block the thyrotropin receptor are produced by a mother who has autoimmune thyroid disease, and these antibodies cross the placenta, blocking the function of the fetal thyroid gland. This form of transient hypothyroidism can persist for several weeks or months; the affected newborn or infant requires thyroxine therapy until the antibodies disappear. Another type of transient congenital hypothyroidism may occur when drugs prescribed for the mother, such as propylthiouracil, methimazole, or iodides, cross the placenta and block the fetal thyroid gland. Iodine-containing medications should be applied to the skin or mucous membranes of neonates sparingly, because the iodine is absorbed easily and excessive iodine

**BOX 273-1 Causes of Hypothyroidism****CONGENITAL HYPOTHYROIDISM**

- A. Thyroid dysgenesis
  - 1. Thyroid aplasia
  - 2. Thyroid hypoplasia
  - 3. Ectopic thyroid gland
- B. Familial abnormalities of thyroid hormone synthesis and metabolism (familial dysmorphonogenesis)
- C. Maternal disease
  - 1. Therapeutic doses of iodine-131 after the 11th week of gestation
  - 2. Transplacental autoimmune thyroiditis
  - 3. Ingestion of goitrogens
- D. Endemic goiter and cretinism
- E. Hypothalamic-pituitary hypothyroidism
  - 1. Pituitary agenesis or aplasia
  - 2. Thyrotropin deficiency: isolated
  - 3. Hypothalamic hormone deficiency
    - a. Isolated thyrotropin deficiency
    - b. Multiple tropic hormone deficiencies
    - c. Septo-optic dysplasia
    - d. Anencephaly
  - 4. Hypothalamic-pituitary lesions

**JUVENILE HYPOTHYROIDISM**

- A. Thyroiditis, autoimmune (Hashimoto thyroiditis)
- B. Congenital thyroid dysgenesis
  - 1. Ectopic thyroid
  - 2. Hypoplastic
- C. Congenital defects in thyroid hormone synthesis or metabolism
- D. Iatrogenic thyroid ablation
  - 1. Surgical
  - 2. Radioactive iodine-131
- E. Ingestion of goitrogens
- F. Endemic goiter
- G. Hypothalamic-pituitary disease

blocks the newborn's thyroid gland. On the other hand, transient iodine deficiency in the newborn can cause temporary hypothyroidism. Rarely, congenital secondary (pituitary) hypothyroidism is caused by mutations in the genes that code for pituitary transcription factors. Milder forms of congenital hypothyroidism may be missed by newborn screening programs, with symptoms not appearing until childhood. Children with these milder symptoms usually have either familial goitrous hypothyroidism (dysmorphonogenesis) or thyroid dysgenesis with an ectopic thyroid gland located somewhere between the foramen cecum of the tongue and the anterior mediastinum. Thyroid hormone levels in the premature newborn are lower than in the term newborn, with the smallest and most premature having the lowest levels. These levels normally increase postnatally, and unless there is evidence for primary hypothyroidism as

indicated by an elevated thyrotropin level, treatment with levothyroxine does not benefit the newborn.

The most common cause of hypothyroidism in children beyond the neonatal period is autoimmune thyroiditis. Similar to other autoimmune conditions, autoimmune thyroiditis is thought to be the result of the interplay between unknown environmental factors and a genetic predisposition, which is itself associated with certain human leukocyte antigen types. Occasionally, patients who have hypothalamic or pituitary disease may be seen initially with hypothyroidism. These children usually have other clinical features to suggest an abnormality of the hypothalamus or pituitary. Up to 23% of obese children may have mild elevations of thyrotropin without decreases in circulating T3 or T4 levels. In these cases, the thyroid abnormalities seem to be the result of obesity, not the converse.

**INCIDENCE**

Congenital hypothyroidism is present at birth and has an estimated incidence in iodine-sufficient regions of the world of approximately 1 newborn for every 4,000 live births, with a female-to-male ratio of 2 to 1. The incidence is greater in iodine-deficient regions. Juvenile-acquired hypothyroidism generally occurs outside the newborn period and is most often caused by autoimmune thyroiditis, also known as Hashimoto or chronic lymphocytic thyroiditis. The incidence of juvenile hypothyroidism in the US population, as defined by elevated serum thyrotropin concentrations, is approximately 2% of children 12 to 19 years of age.

**DIFFERENTIAL DIAGNOSIS**

The range of nonspecific symptoms and physical findings associated with hypothyroidism (Box 273-2) may result in other diagnoses being considered initially. For example, in the newborn, prolonged jaundice may raise concerns about liver abnormalities; however, as discussed later in this chapter, most newborns with congenital hypothyroidism will be diagnosed not based on clinical suspicion, but via newborn screening programs. In older children, other conditions often cause problems that may be suggestive of hypothyroidism. These problems include chronic fatigue in children with depression, delayed growth in children with simple delayed puberty, and weight gain in children with exogenous obesity.

**EVALUATION**

Hypothyroidism can affect many different organ systems to varying degrees. Therefore, a diagnosis of hypothyroidism should be considered when a patient exhibits any of the signs or symptoms listed in Box 273-2. Many of the symptoms and signs of hypothyroidism are different during infancy, compared with childhood, and will be considered separately.

**History**

During the first month of life, affected newborns may have no clinical symptoms or signs of hypothyroidism. In newborns who have no functioning thyroid tissue, clinical symptoms and signs are usually not present at birth, but are almost always present by 6 weeks of age. The clinical symptoms and signs in older children who

### BOX 273-2 Symptoms and Signs of Hypothyroidism

#### HISTORY

##### *Congenital Hypothyroidism*

- Decreased stooling (<1 stool per day)
- Prolonged hyperbilirubinemia (bilirubin >10 mg/dL after 3 days of age)
- Respiratory distress in a term newborn
- Birth weight >4,000 g
- Feeding problems
- Sleepiness
- Hoarse cry

##### *Acquired Juvenile Hypothyroidism*

- Growth retardation (<4 cm/yr)
- Delayed dental development and tooth eruption
- Onset of puberty—usually delayed; rarely precocious
- Menstrual disorders
- Galactorrhea
- Constipation
- Cold intolerance
- Weight gain
- Fatigue

#### PHYSICAL FEATURES

##### *Congenital Hypothyroidism*

- Facial edema
- Large posterior fontanelle (>0.5 cm)
- Rectal temperature <95°F (35°C)
- Umbilical hernia
- Macroglossia
- Bradycardia (pulse <100 beats/min)
- Lethargy
- Cutaneous mottling, vasomotor instability
- Hirsute forehead

##### *Acquired Juvenile Hypothyroidism*

- Delayed bone maturation
- Short stature
- Myopathy and muscular pseudohypertrophy
- Increased skin pigmentation
- Physical and mental torpor
- Pale, gray, cool, mottled, thickened, coarse skin
- Coarse, dry, brittle hair
- Bradycardia
- Delayed deep-tendon reflexes

have acquired hypothyroidism may be subtle and insidious in their development. If the disease has been present for more than 6 months, then growth deceleration should be evident, because normal thyroid hormone secretion is essential for normal linear growth. Hence, many patients who have juvenile hypothyroidism have either thyromegaly or a deceleration of growth and are usually short in stature. Deceleration of linear growth should be identified by

the primary care physician routinely measuring the height of the patient; an early diagnosis will prevent the development of long-standing hypothyroidism, cessation of linear growth, and the risk of a decrease in final adult height. Frank obesity is uncommon in children who have hypothyroidism.

#### Physical Examination

Diagnosing congenital hypothyroidism on clinical grounds is difficult because of the varying manifestations of the disease (Figure 273-1). Some nonhypothyroid newborns may have clinical features suggestive of hypothyroidism and yet have normal thyroid studies. Conversely, some hypothyroid newborns may have minimal clinical features, such as mild periorbital edema, an enlarged posterior fontanelle, decreased stooling, and abdominal distention. Children who have advanced hypothyroidism and myxedema are usually chubby and have periorbital edema. Inspection and palpation of the anterior cervical area enables the examiner to identify an enlarged thyroid gland, even in the neonate. The easiest method for examining the thyroid gland of a newborn is to place the newborn in the supine position with the neck hyperextended over the edge of the examining table and feel for the isthmus of the thyroid, just below the hyoid bone. After identifying the isthmus, the primary care physician should palpate laterally to delineate the lobes, which are difficult to define in a healthy newborn. The thyroid examination of an older child is easier; because the thyroid rises during swallowing, having the patient swallow water will facilitate the identification and delineation of both lobes of the thyroid gland as distinct from other adjacent tissue.

#### Laboratory Evaluation

##### *Thyroid Function Tests*

The most useful thyroid function tests are usually measurement of serum thyrotropin and free thyroxine ( $T_4$ ), the latter of which has widely supplanted the determination of total  $T_4$ . Total  $T_4$  values are significantly influenced by circulating protein concentrations and are therefore less clinically useful. An elevation of the serum thyrotropin value is the most sensitive test result for identifying primary hypothyroidism. The combination of a low serum  $T_4$  value and an elevated thyrotropin value is diagnostic of primary hypothyroidism. A normal free  $T_4$  level and an elevated thyrotropin level are indicative of mild hypothyroidism. In patients with low free  $T_4$  and thyrotropin levels, hypothalamic or pituitary hypothyroidism is strongly suspected and deserves further evaluation. Male patients with normal free  $T_4$  and thyrotropin levels, but low total  $T_4$  levels, are likely to have thyroid binding-protein deficiency, a benign condition. The free  $T_4$  determination by direct dialysis is the most accurate method and the least likely to give false-positive or false-negative results from interfering drugs or other substances in serum. Occasionally, a child or infant who has a coexisting and severe illness may have the nonthyroidal illness syndrome (euthyroid sick) in which the free  $T_4$  level may be low, the serum triiodothyronine ( $T_3$ ) value is low, the thyrotropin value is

**Figure 273-1** A, Normal infant referred at 8 months of age who had clinical signs, but no clinical symptoms of congenital hypothyroidism. B, Infant with documented primary hypothyroidism at 4 weeks of age. Her clinical features at this age were minimal and included only mild periorbital edema, an enlarged posterior fontanelle, decreased stooling, and abdominal distention. C, Infant at age 6 months who has athyreosis and severe congenital hypothyroidism. (From Foley TP Jr. *Sporadic congenital hypothyroidism*. In: Dussault JH, Walker P, eds. *Congenital hypothyroidism*. New York, NY: Marcel Dekker; 1983.)

normal, and the reverse  $T_3$  levels are borderline or frankly elevated.

Tests other than the serum  $T_4$  and thyrotropin determinations are not usually required for children in whom a diagnosis of hypothyroidism is suspected; however, the finding of elevated serum thyroid peroxidase or thyroglobulin antibodies confirms the presumptive diagnosis of autoimmune thyroiditis. Transient congenital hypothyroidism may be caused by thyrotropin receptor–blocking antibodies acquired from the mother who has autoimmune thyroid disease and primary hypothyroidism.

The diagnosis of congenital hypothyroidism is rarely made on clinical grounds; rather, the newborn is identified via a newborn hypothyroidism detection program using a dried blood spot collected in the first 24 to 48 hours of life, which is then analyzed at a central laboratory. In most programs, thyrotropin levels are determined either for all newborns or for newborns whose total  $T_4$  level falls below a threshold value. Newborns identified in these programs must have confirmatory laboratory measurements of free  $T_4$  and thyrotropin performed as soon as possible.

#### Radioisotopic Studies

Although some experts recommend the use of radioisotopic studies for all newborns with suspected congenital hypothyroidism, others do not, and the thyroid scan is listed as an *optional diagnostic study* in the most recent American Academy of Pediatrics (AAP) guidelines. If a thyroid scan is performed, then iodine-123 or technetium-99m should be used rather than iodine-131, which exposes the neonatal thyroid to higher radiation doses. The thyroid scan will

distinguish sporadic disease, such as thyroid dysgenesis, from familial goitrous thyroid dysmorphogenesis, a distinction important for genetic counseling. With dysgenesis, the scan will be consistent with agenesis and atopic thyroid tissue. In familial dysmorphogenesis, a normally sized or enlarged thyroid gland will be found in the normal anterior cervical location of the neck.

Radioisotopic studies are rarely needed in older patients who have juvenile hypothyroidism. Thyroid uptake studies are indicated when the patient has diffuse thyromegaly and biochemical evidence of hypothyroidism not caused by autoimmune thyroiditis or goitrogen ingestion. However, it may be necessary to perform an ultrasound or, rarely,  $^{123}\text{I}$  scintigraphy, in case a nodule is felt. In these cases, biopsy or excision biopsy may be necessary to rule out any neoplasm. Although not essential, the assessment of skeletal maturation can provide additional data regarding the duration of hypothyroidism. A bone age determination consistent with that of a healthy newborn would suggest recently acquired, mild, congenital hypothyroidism, whereas notation of the absence of ossification centers at the knee, in addition to the presence of only the 2 ossification centers in the foot, indicates that the fetus was affected by hypothyroidism during the third trimester of pregnancy. In children, a significantly delayed bone age indicates long-standing and severe hypothyroidism and may aid in guiding long-term therapy.

#### MANAGEMENT

The treatment of choice for hypothyroidism in infancy and childhood is the daily administration of oral L-thyroxine (Table 273-1).

**Table 273-1** Doses of L-Thyroxine Used to Treat Hypothyroidism in Infancy and Childhood

AGE	T <sub>4</sub> DOSE/DAY (MCG)	T <sub>4</sub> DOSE/KG/DAY (MCG)
Full term	50	10–15
<6 mo	25–50	8–10
6–12 mo	50–75	6–8
1–5 yr	75–100	5–6
6–12 yr	100–125	4–5
>12 yr	100–200	2–3

T<sub>4</sub>, Thyroxine.

### Congenital Hypothyroidism

The initial L-thyroxine dose in a term newborn is 50 mcg daily for the first 1 to 2 weeks and should be started promptly at the initial visit when screening test results are abnormal and serum samples have been sent for confirmatory tests or, whenever the scan is abnormal. Newborns who have hypothalamic or pituitary hypothyroidism generally have milder hypothyroidism and should be given 25 mcg/day. At the end of the second and fourth week, serum T<sub>4</sub> and thyrotropin values should be measured to verify that the amount of L-thyroxine is adequate, but not excessive. Clinical studies have indicated that the more rapid normalization of serum free T<sub>4</sub> and thyroid-stimulating hormone levels with initial dosing of 50 mcg L-thyroxine daily is associated with better long-term development outcomes than is using 37.5 mcg daily initially. After 1 or 2 weeks, the 50-mcg/day dose may need to be reduced to 37.5 g/day and infrequently to 25 mcg/day if clinical symptoms of hyperthyroidism develop or if the serum T<sub>4</sub> value exceeds 16 mcg/dL. In athyrotic newborns who have low T<sub>4</sub> values, usually 50 mcg/day is adequate. The AAP guidelines for monitoring free T<sub>4</sub> and thyrotropin values are outlined in Table 273-2. However, it should be noted that recent data suggest that more frequent testing between the ages of 6 months and 3 years may be needed.

Therapy should be adjusted to maintain the serum T<sub>4</sub> levels during infancy in the upper half of the age-adjusted normal range to optimize developmental outcome. Concomitant administration of soy formula, iron, calcium, simethicone drops, and high-fiber foods may interfere with absorption of the L-thyroxine and should be avoided when possible. Compounding of liquid suspensions from levothyroxine tablets by local pharmacists should be discouraged, as the dose delivered to the newborn or infant may be inconsistent. Occasionally the thyrotropin value will not return to normal even if the T<sub>4</sub> dose is excessive and causes clinical thyrotoxicosis. These babies may have an abnormality in the feedback set point of thyrotropin secretion. The goal of therapy in this situation should be to maintain normal serum T<sub>4</sub> values and clinical euthyroidism. Discontinuing L-thyroxine therapy some time after 3 years of age is a way of testing for

**Table 273-2** American Academy of Pediatrics Guidelines for Monitoring Congenital Hypothyroidism\*

AGE	INTERVAL
<6 mo	Every 1–2 mo
6 mo–3 yr	Every 3–4 mo
3 yr–completion of growth	Every 6–12 mo

\*Recheck thyroxine and thyroid-stimulating hormone 2 to 3 weeks after starting therapy.  
From Rose SR; American Academy of Pediatrics Section on Endocrinology and Committee on Genetics, American Thyroid Association, Brown RS; Public Health Committee, Lawson Wilkins Pediatric Endocrine Society. Update of newborn screening and therapy for congenital hypothyroidism. *Pediatrics*. 2006;117(6):2290–2303.

transient congenital hypothyroidism. Serum T<sub>4</sub> and thyrotropin levels are then determined 2 to 4 weeks later. This trial period off therapy is not necessary for patients documented to have thyroid aplasia, ectopic thyroid dysgenesis, or elevated thyrotropin values after the initial period of therapy. Mild sensorineural hearing impairment may be fairly common in congenital hypothyroidism and should be screened for to allow early intervention.

### Acquired Hypothyroidism

Older children who have hypothyroidism do not share the same degree of urgency in achieving the euthyroid state. Although patients who have had a recent onset of mild hypothyroidism may be given a full replacement dose of L-thyroxine, children 3 years and older who have chronic hypothyroidism and clinical symptoms should be given a low dose that is gradually increased every 2 to 4 weeks to the full replacement dose. The rapid correction of the hypothyroid state can often be associated with undesirable behavioral side effects. These children act as though they are thyrotoxic despite biochemical euthyroidism; they are often restless, have a short attention span, and are emotionally labile. In such cases, a gradual increase in dose seems to minimize these problems in adjustment from the hypothyroid to the euthyroid state. Adequacy of L-thyroxine therapy is monitored by free T<sub>4</sub> and thyrotropin determinations every 6 to 12 months once the patient is receiving a full replacement dose with normal values. An elevated thyrotropin level with or without a low T<sub>4</sub> value indicates either inadequate therapy or poor compliance; the latter is often characterized by variable serum T<sub>4</sub> and thyrotropin values. For example, the levels may be normal on one occasion, but discordant (normal or elevated T<sub>4</sub> value with elevated thyrotropin value) on subsequent determinations, despite no change in therapy.

### PROGNOSIS

Most infants who were treated adequately for congenital hypothyroidism since the first month of age have an excellent prognosis for normal intellectual function and linear growth. However, delays in diagnosis and institution of adequate therapy are usually associated with an

increased risk of intellectual disability. Also, infants who have severe fetal hypothyroidism indicated by delayed skeleton maturation and very low  $T_4$  values have an increased risk for impaired intellectual function. In contrast, no permanent intellectual impairment is found among patients who have juvenile hypothyroidism. Adolescents who have chronic hypothyroidism and severe growth retardation may never achieve their full growth potential. In many cases, their linear growth response to therapy is not accelerated, and the height percentile achieved as an adult is lower than that predicted by their growth before the development of hypothyroidism.

### WHEN TO REFER

- Severe congenital hypothyroidism.
- The cause of hypothyroidism is not established on the initial evaluation.
- Initial therapy does not normalize thyroid function test results within the normal range for age, which is often not necessarily the normal range provided by the laboratory. The physician must know the normal range of thyroid function test results for age for patient management during the first 2 decades of life.
- Acquired hypothyroidism is atypical or complex. The disease occurs in infancy or early childhood or is associated with other endocrine or nonendocrine autoimmune diseases.
- When the diagnosis is hypothalamic or pituitary hypothyroidism based on a low free  $T_4$  level (by a method validated in infants and children) and normal or low thyrotropin level. Rarely is this form of hypothyroidism an isolated disease. It is expected to be associated with other hypothalamic-pituitary abnormalities; if it is isolated, then genetic evaluation is needed to define the cause and potential for recurrence in a family.

### WHEN TO ADMIT

- Myxedema coma
- Parental nonadherence with treatment of the newborn, infant, and young child who is at increased risk for permanent impairment of central nervous system function if thyroid function test results are not maintained in the normal range.

### Chapter 274

## IMMUNE (IDIOPATHIC) THROMBOCYTOPENIA PURPURA

Jawhar Rawwas, MD

Immune thrombocytopenic purpura (ITP) of childhood is an acquired immune-mediated, and usually self-limited, condition of low platelet counts. ITP is caused by antibodies (mostly immunoglobulin G [IgG]) directed against antigens normally present on platelet membranes such as glycoproteins IIb/IIIa and Ib/IX. The antibody-coated platelets are then recognized and destroyed by reticuloendothelial cells found mostly in the spleen. There is increasing evidence that cellular immune mechanisms play an important role in ITP. The production of antiplatelet antibodies by B cells requires antigen-specific, CD4<sup>+</sup> helper T cells, and cytotoxic T cells may play a role in the destruction of platelets and influence platelet production.

### INCIDENCE

The incidence of ITP is estimated to be between 4 and 8 cases per 100,000 children annually, but the rate is likely higher because of subclinical cases. ITP is most common in children ages 2 to 10 years, with a peak incidence at 2 to 4 years of age. A history of a preceding infection, subsequently resolved, is elicited in most patients. In some cases, ITP is seen after measles, mumps, and rubella (MMR) immunization. The best estimate of absolute risk for ITP with MMR vaccination is 1 in 24,000 doses and usually occurs within 6 weeks of vaccination. This number is considerably less than ITP that occurs after natural infections with measles, mumps, or rubella. More than 70% of cases of ITP occur after virus infections. Persistent or chronic ITP has been associated with HIV, hepatitis C virus, and *Helicobacter pylori* infections in adults and possibly in children from high-prevalence populations. In children, both sexes are equally affected, but female predominance over boys (2.3:1) is seen during adolescence and adulthood.

## CLINICAL PRESENTATION

A child with ITP typically has sudden onset of petechia, purpura, and ecchymosis in the absence of other signs of illness. A history of a recent viral illness usually exists. Mucosal (nose, mouth, and gingival surfaces) bleeding may be present. The Intercontinental Childhood ITP Study Group (ICIS) conducted a prospective registry defining severe hemorrhage at diagnosis and during the following 28 days in children with ITP. Of 863 eligible and evaluable patients for bleeding severity assessment at diagnosis and during the subsequent 4 weeks, 2.9% had severe bleeding at diagnosis and 0.6% had new severe hemorrhagic events during the ensuing 28 days, suggesting that severe bleeding is rare in ITP over the first month of diagnosis. Intracranial hemorrhage (ICH), the most serious complication of ITP, is rare, occurring in 0.1% to 1% of acute ITP cases. Other than these manifestations of thrombocytopenia, patients with ITP usually have no significant abnormalities on history and physical examination. Other systemic symptoms, such as fever, weight loss, and bone or joint pain, are absent. On physical examination, no significant enlargement of lymph nodes, liver, or spleen is present. If any of these symptoms or physical findings is present, then the case is not typical of ITP, and other diagnoses should be considered.

## EVALUATION

For a patient with mucocutaneous signs of bleeding who is otherwise healthy, a reasonable workup includes obtaining a complete blood count, peripheral blood smear, reticulocyte count, blood typing, and direct antiglobulin test (Coombs test). In children with ITP, thrombocytopenia is usually the only laboratory abnormality, and the platelet count is usually lower than 20,000/mcL. A peripheral blood smear will reveal morphologically normal white blood cells and red blood cells (RBCs). Because acute leukemia can present much like ITP with thrombocytopenia and related symptoms of bruising or bleeding, examination of the peripheral smear by a hematopathologist in the setting of suspected ITP is essential to exclude the presence of leukemic blasts in circulation. Large, freshly produced platelets are usually seen. These young reticulated platelets contain messenger RNA and are metabolically active, which may explain why patients with ITP do not bleed as severely as patients with bone marrow failure who have similarly low platelet counts. If other abnormalities are seen on the peripheral smear, then obtaining additional tests such as viral antibodies (HIV, cytomegalovirus, Epstein-Barr virus, varicella, rubeola, mumps, or parvovirus, depending on the clinical picture) or tests for rheumatologic and other hematologic conditions (eg, leukemia, bone marrow failure) may be indicated.

The reticulocyte count is a helpful test when the diagnosis of ITP is not straightforward, such as in cases in which associated mild anemia exists, which is not a rare occurrence. The purpose of blood typing is not transfusion but determination of Rh status, which determines whether a patient is treatable with anti-D antibodies. Both reticulocyte count and blood typing

are not strictly needed for evaluation, but blood should be drawn and kept aside for reticulocyte count and blood typing if needed instead of performing multiple traumatic blood draws on a thrombocytopenic child. Direct antiglobulin test (Coombs test) is recommended to rule out the possibility of associated anti-RBC antibodies as seen in Evans syndrome. In the absence of associated anti-RBC antibodies and in the absence of hemolysis, the mean corpuscular volume (MCV) of RBCs should be normal. If the MCV is increased in the setting of thrombocytopenia, additional evaluation should be done to exclude a clonal abnormality such as that seen in Fanconi anemia.

Although ITP is caused by platelet antibodies, platelet antibody tests are sensitive but not specific, and therefore they are not indicated for the diagnosis of acute ITP in children. In ITP, bleeding time is prolonged, but assessment of bleeding time is an unnecessary test and is traumatic and inaccurate in children. Prothrombin time and activated partial thromboplastin time are normal and are also unnecessary tests. In the past, many pediatric hematologists performed a bone marrow aspiration on patients with ITP to exclude acute lymphocytic leukemia, especially before starting a patient on steroids, for fear of partially treating and thus masking a leukemic process. Now, pediatric hematologists prefer to perform bone marrow aspiration and biopsy only on patients who have clinical or laboratory features that are atypical of ITP at presentation, for example a significantly increased MCV, suggesting an alternate diagnosis such as acute leukemia or a bone marrow failure syndrome.

Marrow examination is also indicated for patients who are initially diagnosed as having ITP but who do not respond to treatment. Response to intravenous immunoglobulin (IVIG) or anti-D antibodies is usually seen within 1 to 2 days and to steroids within 1 week. The choice as to when to perform a bone marrow evaluation is an individualized decision. The most likely time for the bone marrow examination to be performed is between 7 and 14 days after treatment is begun and when response to treatment is poor. Bone marrow examination should also be considered in patients who have an atypical clinical course, in patients in whom splenectomy is contemplated, for additional confirmation of the diagnosis of ITP, and to rule out any possibility of a malignant process. The bone marrow in ITP is cellular, with normal erythroid and myeloid precursors, and usually shows increased numbers of megakaryocytes.

## DIFFERENTIAL DIAGNOSIS

Immune thrombocytopenic purpura is a diagnosis of exclusion after considering the likelihood of other causes of isolated thrombocytopenia. These causes include the following:

1. Infections such as Epstein-Barr virus, hepatitis C virus, and HIV type 1. These can be ruled out by history and physical examination, and, if needed, by obtaining liver function tests and viral studies.
2. Drugs such as heparin and sulfonamides. These can be ruled out by history.
3. Other autoimmune diseases, such as systemic lupus erythematosus, which may be difficult to diagnose.

These autoimmune diseases are more likely to affect teenagers and adults than younger children. Common variable immunodeficiency (CVID) and autoimmune lymphoproliferative syndrome (ALPS) should be considered in cases of multiple autoimmune cytopenias.

4. Acute leukemia or bone marrow failure. Children with leukemia usually have other symptoms along with abnormal physical findings, especially hepatosplenomegaly and lymphadenopathy, which are absent in ITP. Leukocytosis (white blood cell count  $>10,000/\text{mcL}$ ) and significant anemia (hemoglobin count  $<10/\text{dL}$ ) are usually seen in leukemia, but not in ITP. In acquired aplastic anemia, a low platelet count is usually associated with other significant changes in the peripheral blood, such as macrocytic anemia, leukopenia, or neutropenia.
5. Destructive thrombocytopenias, such as thrombotic thrombocytopenic purpura (TTP) and disseminated intravascular coagulation (DIC), although patients with these conditions present with other clinical and laboratory abnormalities and are usually sicker at presentation than ITP patients.
6. Inherited thrombocytopenia. Although thrombocytopenia in most children is either autoimmune or drug related, keeping this category in mind is important. Eliciting a family history of thrombocytopenia, especially parent-child or maternal uncle-nephew, may be important. Diagnostic features on a peripheral smear such as abnormal size of platelets (either small or giant); absence of platelet alpha granules (gray platelets); Döhle-like bodies, or microcytosis may point to an inherited thrombocytopenia. Clinically, bleeding out of proportion to the platelet count, onset of thrombocytopenia early in life, and associated features such as absent radii, intellectual disability, renal failure, high-frequency hearing loss, cataracts, and history of a stable level of thrombocytopenia for years suggest inherited thrombocytopenia.
7. Type 2B von Willebrand disease is a condition that results in increased spontaneous binding of the high-molecular-weight von Willebrand factor (vWF) multimers to platelets, which can lead to increased clearance of platelets from circulation, resulting in variable thrombocytopenia. This condition is usually of autosomal dominant inheritance, so obtaining family history regarding mucocutaneous bleeding is important. If suspected, vWF studies including multimer analysis should be done in consultation with a hematologist.

## MANAGEMENT

Pediatric hematologists differ in their approach to the management of children with ITP. Approximately 80% of children with ITP will recover within a few months, with or without treatment. Early treatment has not been shown to alter the risk for occurrence of intracranial hemorrhage. Patients whose platelet counts do not return to normal ( $>150,000/\text{mcL}$ ) within 6 months were historically defined as having chronic ITP. In an effort to standardize definitions and criteria of response in ITP, an international work group suggested coining a new category, called *persistent ITP*, to define the period lasting between 3 and 12 months

from diagnosis. This category includes patients not achieving spontaneous remission or not maintaining their response after stopping treatment between 3 and 12 months from diagnosis. The chances of spontaneous remissions are still significant during this period, making deferral of more aggressive therapeutic approaches reasonable. The term *chronic ITP* will be reserved for patients with ITP lasting for more than 12 months. Early treatment does not alter the natural course of ITP and does not affect the development of chronic ITP.

## GENERAL ADVICE

General useful advice to families with an affected child includes avoiding activities that are associated with increased likelihood of trauma such as contact sports, making sure that children use helmets when riding bicycles, and avoiding medications that interfere with platelet function such as aspirin and nonsteroidal anti-inflammatory drugs.

## INTRACRANIAL HEMORRHAGE

Even though ICH is rare, it is the most likely cause of death in ITP. Recognizing which patients are more likely to develop ICH is difficult. A literature review of 62 reported pediatric and adolescent cases of ICH in the setting of ITP showed that the median time from the diagnosis of ITP to ICH was 32 days (range, 0 days to 8 years), and 72% of cases occurred within 6 months of diagnosis. The platelet count was less than  $10,000/\text{mcL}$  in 71.4% of the cases. Treatment before the ICH was primarily steroids but also included IVIG, splenectomy, and others. A significant number of patients developed ICH despite having already initiated steroid treatment of ITP. Many patients with ICH have other risk factors, including preceding head injury, other preceding mucocutaneous bleeding, prior aspirin treatment, and arteriovenous malformations.

Management of ICH in the setting of ITP is an emergency that requires immediate imaging (computed tomographic scan) to determine the location and extent of the bleeding and immediate consultation with a pediatric intensivist, hematologist, neurosurgeon, and general surgeon. Treatment includes the administration of IVIG, steroids, continuous platelet transfusions to rapidly increase the platelet count, and surgical intervention, if needed, including craniotomy (especially with posterior fossa hemorrhages that are more likely to cause herniation or brainstem compression) and possibly splenectomy.

## MANAGING BLEEDING

Any intervention in a patient with ITP is directed at early control of symptoms, such as stopping bleeding and preventing recurrent bleeding. Most ITP cases in children can be managed on an outpatient basis. Although the consensus is that treatment is indicated for the patient with overt bleeding, the nature of the treatment and the question of management recommendations for patients with ITP who have different clinical manifestations remain a subject of debate. Therefore current therapy recommendations are not evidence based but based on expert consensus opinions.

The American Society of Hematology guidelines suggest that children with ITP who have platelet counts greater than 30,000/mcL require no treatment if they have few or no symptoms, as is usually the case. Patients with platelet counts between 10,000 and 30,000/mcL have treatment recommendations based on the presence and severity of associated bleeding symptoms or the risk for bleeding. Because the severity of symptoms depends on the degree of thrombocytopenia, the lower the platelet count, the more likely the patient is to receive treatment, even in the presence of relatively mild symptoms. Patients with extensive purpura of the mucosal membranes may have a higher bleeding risk and should be treated more often than not. Children with platelet counts below 10,000/mcL and only minor purpura are usually treated. Children with any concomitant or preexisting bleeding disorder should also be treated.

Other important factors that play a role in the decision regarding treatment include the age of the child and his or her degree of activity. Social variables such as the reliability of the caregivers and ease of access to emergency medical care always play a role in the decision to treat or not to treat.

When therapy is indicated, the primary treatment options for the newly diagnosed patient with ITP are corticosteroids, IVIG, or intravenous anti-D immunoglobulin. All of these agents are effective in shortening the duration of thrombocytopenia. Platelet transfusions are only temporarily effective because the transfused platelets are destroyed, but they are to be used in cases of emergency.

### TREATING WITH CORTICOSTEROIDS

Corticosteroids have been used for many years for the management of ITP in all age groups. Steroids reduce the risk for symptoms in patients with ITP by different mechanisms but most likely by reducing reticuloendothelial system phagocytosis of antibody-coated platelets. Most pediatric hematologists use prednisone for 2 to 3 weeks. Shorter courses at higher doses are also effective. Intravenous or oral methylprednisolone for up to 3 to 7 days and dexamethasone for 4 days every 4 weeks have been given. About 75% of patients with ITP respond to steroids, and the response is faster when higher doses are given; thus response can be seen as early as 72 hours after starting treatment. However, platelets usually decrease after the steroids are discontinued if the titer of platelet antibodies remains elevated. A second course of treatment may be necessary if bleeding develops or if the platelet count drops to fewer than 10,000/mcL. Side effects of brief courses of corticosteroids include behavioral changes, sleep disturbance, increased appetite, hyperglycemia, and weight gain. These side effects are more pronounced at higher dose levels. Caution should be taken when using steroids in the setting of active infection, especially with varicella infection.

### TREATING WITH INTRAVENOUS IMMUNOGLOBULIN

Rapid improvement in platelet numbers in patients with ITP who are receiving IVIG, usually within 24 hours, is seen compared with patients receiving

steroids. Response to IVIG is seen in more than 80% of treated patients. IVIG likely interferes with Fc receptor activity, resulting in prolonged survival of antibody-coated platelets. Other mechanisms of action for IVIG include regulatory properties of antibodies in IVIG as well as the IVIG effects on cytokine synthesis and on receptors for cytokines and complement. One intriguing proposal for the mechanism of action is that concentration-dependent elimination of IgG can be found from the plasma and that IVIG administration causes acceleration of the rate of IgG catabolism. Such a process would eliminate individual IgG molecules in direct proportion to their relative concentration in plasma. Thus elimination of antiplatelet antibodies is accelerated.

Side effects of IVIG include chills, fever, headache, and nausea and vomiting. Side effects tend to be more pronounced in older patients. Neutropenia (absolute neutrophil count, <1,500/mcL) develops in approximately 30% of patients. In addition, IVIG is far more expensive than steroid therapy.

### Treating With Anti-Rho(D)

Anti-Rho(D) immunoglobulin binds to the D antigen in Rh-positive individuals, and the antibody-coated RBCs block the Fc receptor of reticuloendothelial cells, resulting in a rapid increase in platelet count, usually in 1 to 2 days. The dose regimen commonly used is a single dose of 50 to 75 mcg/kg. This achieves an increase in platelet count that is comparable to what is seen with IVIG therapy. Response rate is about 50% to 77%, depending on the dose used. An average drop in the hemoglobin level of approximately 1.3 g is seen as a result of the mild hemolysis of the patient's Rho(D)-positive red cells. Anti-Rho(D) should be used with caution in children with preexisting anemia, and it should probably be given only to children with a hemoglobin level greater than 10 g/dL and after consultation with a pediatric hematologist experienced with its use. With increased use of anti-Rho(D), there have been a few cases of patients developing increased hemolysis leading to severe anemia, acute renal insufficiency, DIC, and multisystem organ failure; therefore it should always be used with caution. It is recommended that patients treated with anti-Rho(D) receive intravenous fluids and be observed for the development of hematuria and hemoglobinuria for at least 8 hours. Signs and symptoms of intravascular hemolysis include back pain, shaking chills, fever, and discolored urine or hematuria. Absence of the signs and symptoms of intravascular hemolysis within 8 hours does not indicate that intravascular hemolysis cannot occur subsequently. Laboratory evaluation for intravascular hemolysis includes plasma hemoglobin, haptoglobin, lactate dehydrogenase, and plasma bilirubin (direct and indirect).

### FOLLOW-UP

Patients should have blood counts done once or twice weekly for follow-up. In most cases, with early recovery, complete resolution of the thrombocytopenia occurs in 2 to 3 months. When the platelet count is stable, greater than 30,000/mcL, or increasing with time, blood counts should be done less frequently.

## OUTCOMES

Treatment does not alter the course of ITP (ie, the incidence of patients who go on to develop chronic ITP); however, it does shorten the duration of thrombocytopenia in some patients. For typical cases of childhood ITP, 80% of patients will have the platelet counts return to normal within 2 months of presentation, with or without therapy. Another 10% will recover normal platelet levels in the next few months, and about 10% will go on to have chronic thrombocytopenia (>6 months' duration). Approximately 25% of children with ITP will have a relapse after initial treatment. The 25% of patients who will have a relapse after initial treatment consists of 10% who will have chronic ITP, 10% who will have recurrence but resolution within 6 months, and 5% who will have episodes of ITP recurrences and remissions throughout their lives.

## COMPLICATIONS

Approximately 15% to 20% of all pediatric patients with ITP develop moderate or major hemorrhagic problems. Life-threatening bleeding, including ICH, is rare, with an incidence of 0.1% to 1%. When ICH or any other life-threatening hemorrhage occurs, immediate interventions, including IVIG and high-dose steroids, platelet transfusions, and emergency splenectomy, should be considered. For patients with ITP who are unstable or have progressive ICH, emergency craniotomy may be necessary.

### Immune Thrombocytopenia in the Neonate

Most neonatal thrombocytopenia is not immune in nature but is caused by sepsis, congenital infections, drugs, asphyxia, and necrotizing enterocolitis. Two conditions occur when immune thrombocytopenia is seen in neonates. Neonatal alloimmune thrombocytopenia (NAIT) is a condition whereby the mother develops antiplatelet antibodies directed against specific antigens found on fetal platelets but lacking on hers. An associated 20% risk for ICH occurs, and treatment usually involves administration of maternal washed platelets and IVIG. The importance of detection and accurate diagnosis of NAIT is in the ability to prevent complications in future pregnancies by treating the mother with IVIG and steroids as well as performing in utero blood sampling and intervening in case of thrombocytopenia. Parental platelet typing may help define the risk for development of NAIT in future pregnancies. A hematologist and a high-risk fetal-maternal specialist should be involved in the management of patients with NAIT. Another less serious condition is that resulting from passive transfer of maternal platelet autoantibodies in a mother with ITP. Only 4% of babies born to mothers with ITP have platelet counts less than 20,000/mcL. The risk for ICH is low (<1%), and no proof exists that cesarean delivery alters that risk. Neonatal ITP usually resolves within a few weeks as the antibodies are used up, but physicians may choose to treat the babies with IVIG in case the platelet count drops to less than 30,000/mcL. Maternal ITP is not a contraindication to breastfeeding.

### Chronic Immune Thrombocytopenic Purpura

Chronic ITP is defined as persistence of thrombocytopenia lasting for more than 12 months from the time

of diagnosis. Approximately 10% of patients with typical ITP develop chronic thrombocytopenia. In a prospective Dutch study, variables that predicted the development of chronic disease included a platelet count greater than 10,000/mcL at the onset, the absence of infection shortly before the onset of the disease, and the 232I/T Fc receptor IIB genotype. In another meta-analysis, female gender and older age (>11 years) at presentation, among other variables, correlated with increased likelihood of developing chronic ITP. Management of children with chronic ITP should focus on minimizing the individual's risk for bleeding and maintaining a safe platelet count, knowing that many patients will require no treatment. Given sufficient time (even years), a significant proportion of such patients will improve or remit. If treatment is needed, periodic short courses of steroids may be given. In case of chronic need for steroids, alternate-day dosing may be effective in preventing bleeding while reducing side effects. IVIG and anti-Rho(D) have also been used in patients with chronic ITP, but these measures are only temporary. Some patients with chronic ITP may be good candidates for splenectomy. All children with refractory ITP should be referred to a pediatric hematologist.

The same principles of treatment of acute ITP apply to a certain extent to management of chronic ITP. Other options of therapy include splenectomy, immunosuppressive therapy, rituximab, and thrombopoietin (TPO) receptor agonists.

### Splenectomy

Splenectomy is effective in improving the platelet count and reducing the associated risk for bleeding in 60% to 90% of children with chronic ITP. However, the anticipated improvement in hemostasis and platelet count must be balanced with the consideration of the small but real risk for overwhelming postsplenectomy sepsis, which may be life-threatening. In practice, splenectomy in children with chronic ITP is now rarely performed. If contemplated, splenectomy is usually delayed until the child is older than 5 years because the risk for overwhelming sepsis decreases with age. Presplenectomy immunizations and subsequent penicillin prophylaxis are necessary for all age groups. No universally accepted standards for the timing of splenectomy in chronic ITP exist, but the American Society of Hematology guidelines recommend waiting until at least 12 months after diagnosis, if possible. Platelet counts in splenectomized patients are generally monitored for an indefinite period; any drop in platelet counts or increase in symptoms should prompt an assessment for the presence of an accessory spleen. If not previously done, then recommendations are to perform a bone marrow biopsy on patients who are being considered for splenectomy.

### Immunosuppressive Therapy

For the treatment of refractory chronic ITP with clinically severe course, several agents are available. Examples of immunosuppressive drugs used include cyclosporine and cyclophosphamide. Immunosuppressive therapy should be directed by a pediatric hematologist or oncologist.

### Rituximab

Rituximab, a chimeric murine-human anti-CD20 monoclonal antibody, has also been successfully used. Rituximab acts by destroying B lymphocytes by activating complement-dependent and antibody-dependent cellular toxicity. Therefore the mechanism of action is a slow but effective decrease in the production of antibodies. In a study of 24 patients (2 to 19 years of age) who received 375 mg/m<sup>2</sup> of rituximab in 4 weekly doses, 63% achieved complete remission for 4 to 30 months (platelet count >150,000/mcL). Rituximab use may be associated with infusion-related reactions and with the development of transient hypogammaglobulinemia. Although long-term remissions have been documented, the use of rituximab in the treatment of ITP is relatively recent, and long-term follow-up may be needed for accurate prognostication.

### Thrombopoietin Receptor Agonists

A number of studies with TPO receptor agonists have shown encouraging results in adults. Some children have been successfully treated, and new information about safety and response is emerging. Assuming that the long-term safety of these agents is confirmed, they could be useful in the management of children. There is some evidence that TPO levels are suboptimal in ITP. There is also evidence that there is decreased production of platelets in ITP and that the problem is not limited to increased platelet destruction. Treatment with TPO receptor agonists, however, does not treat the cause of the ITP, and thrombocytopenia recurs when these medications are discontinued.

#### WHEN TO REFER

- History of fevers or bone pain
- Hepatomegaly, splenomegaly, significant lymphadenopathy
- Family history of thrombocytopenia
- Platelet count less than 20,000/mcL
- Abnormal white blood cell count or peripheral smear or associated anemia
- Absence of response to initial therapy

#### WHEN TO ADMIT

- Significant bleeding symptoms
- Severe anemia
- Significant concern for possible traumatic injury
- Any neurologic change in the setting of thrombocytopenia

### Chapter 275

## INFECTIOUS MONONUCLEOSIS AND OTHER EPSTEIN-BARR VIRAL INFECTIONS

Leonard R. Krilov, MD

### EPIDEMIOLOGY

Infection with Epstein-Barr virus (EBV), a member of the herpesvirus group, is extremely common but often not apparent clinically. In Africa a strong association exists between infection with EBV and development of Burkitt lymphoma and nasopharyngeal carcinoma; this association, however, has been demonstrated less clearly in Western countries where infection with EBV often occurs at a later age. In the United States, interest in EBV infection focusses on the typical clinical syndrome—*infectious mononucleosis*—and on its emerging relationship with an increasing number of tumors, noted for the most part in immunocompromised patients.

In childhood, EBV infection is usually inapparent clinically or characterized by a nonspecific, uncomplicated episode of upper respiratory tract infection or pharyngitis. Although EBV antibodies are developed in 70% to 90% of children from low socioeconomic groups by age 5 years, these antibodies occur in only 40% to 50% of those from high socioeconomic groups. Primary infections that do not occur until adolescence and young adulthood are much more likely, for reasons that are unclear, to produce infectious mononucleosis. Thus the annual incidence of infectious mononucleosis is highest among white high school and college students, approximately 1 in 2,500 students. Usually, infection follows entry of EBV into the oropharynx, and its collection from this site can be documented up to 16 months after illness. Apparently, EBV establishes latency in the epithelial cells of the oropharynx, and the virus is periodically shed from this site throughout an individual's lifetime. Transmission from one individual to another seems to occur most often from contact with saliva (thus its description as the *kissing disease*). In the absence of such contact, transfer of infection is less likely. In a study of families that have a childhood index case of infectious mononucleosis, seroconversion occurred in 34.6% of the susceptible siblings over a period of several months. Even though the rate of transmission of the EBV infection was relatively low and slow, the development of infectious mononucleosis was quite high (55.6%) in sibling contacts who showed seroconversion. Secondary infection in typical college settings is lower.

### CLINICAL PRESENTATION

After an incubation period of 2 to 6 weeks (usually 20 to 30 days), signs of classic infectious mononucleosis are seen: fever, severe sore throat, and lymphadenopathy. This constellation of symptoms and signs may be preceded by vague symptoms of fatigue, malaise, and anorexia.

Because infectious mononucleosis is the result of a systemic viral infection, every organ system may be involved. Clinical manifestations compatible with infectious mononucleosis are listed in Figure 275-1.

The fever is usually not higher than 103°F (39.5°C), but the sore throat, frequently accompanied by tonsillar exudate (or in adolescents, more likely a grayish-white necrosis of the tonsillar surfaces) and a palatal enanthem, can be excruciating. Lymphadenopathy, perhaps the most striking feature of the illness, can be limited to the cervical nodes but can also be so extensive as to involve virtually all lymph node groups. Posterocervical adenopathy is frequently noted. The lymph nodes are not usually intensely tender and rarely demonstrate other signs of inflammation. However, palpation of the neck can elicit moderate to severe pain as reflection of the intense inflammation of the pharynx and surrounding tissue.

Enlargement of the spleen and possibly the liver, together with posterocervical adenopathy, is the physical sign that should alert the physician to the possible diagnosis of infectious mononucleosis. Some patients with this illness, however, lack palpable splenic enlargement; massive enlargement of the spleen suggests an alternative diagnosis. Liver enzyme levels are elevated in virtually all patients, but jaundice is infrequent.

A rash, which can be erythematous, petechial, erythema multiforme-like, urticarial, or scarlatiniform, develops in approximately 20% of children who have this illness. A rash develops in 70% to 90% of young adult patients and in a proportion of younger children treated with ampicillin or amoxicillin during acute EBV infection. In some cases the ampicillin-related rash will appear after the medication has been discontinued.

The severity of illness is extremely variable, and some individuals may have relatively few manifestations of infection, whereas others will demonstrate virtually all the symptoms listed in Figure 275-1. In general, the acute clinical manifestations of the illness last approximately 2 to 3 weeks, with peak involvement during the second week. Upper eyelid edema (Hoagland sign) occurs in about 25% of patients.

### DIAGNOSIS AND SEROLOGIC FINDINGS

Infectious mononucleosis is diagnosed by the presence of a triad of typical clinical, hematologic, and serologic findings. In addition to the clinical profile described in the preceding section, minimal hematologic features should include a lymphocytosis of 50% or more of all leukocytes and an atypical lymphocyte count of 10% or more of all leukocytes. Other general

**Figure 275-1** Frequency of clinical findings in 2 age groups of children with documented Epstein-Barr virus infectious mononucleosis: younger than 4 years and 4 to 16 years of age. (From Sumaya CV, Ench Y. Epstein-Barr virus infectious mononucleosis in children. I. Clinical and general laboratory findings. *Pediatrics*. 1985;75:1003-1010.)

laboratory findings usually include a decline in the number of granulocytes and platelets.

Paul-Bunnell antibodies are not EBV specific but are heterophilic immunoglobulin M (IgM) produced by EBV-infected B cells and react with horse, sheep, and cow erythrocytes, but not with guinea pig kidney cells. These are the basis for most rapid “mono” tests but will be present in 50% or fewer of children younger than 4 years. Among school-aged children and young adults, Paul-Bunnell antibody is detectable 80% to 90% of the time during the second week of clinical illness. Occasionally the heterophil response will be brief and minimal, particularly in young children, or will occur late in the illness. Therefore results are often negative early in the course of the illness. Commercial diagnostic kits, which rely on differential red blood cell adsorption to detect the heterophile antibody, are readily available and easy to use in a physician’s office; they are 96% to 99% sensitive when the antibody is present and give a result in 2 minutes. False-positive results can occur in cases of rubella, hepatitis, serum sickness, drug reactions, and systemic lupus erythematosus and through improper use of the kit or inaccurate interpretation of the agglutination reaction. The magnitude of the heterophile antibody titer does not correlate with clinical severity, and repeat testing, once a positive test result is obtained, provides no additional information regarding waxing or waning of the illness beyond that gained from clinical assessment of the patient. Heterophile tests can remain positive for years and are not useful in testing after the initial episode of mononucleosis if similar symptoms reappear.

If heterophile test results are negative and EBV infection is strongly suspected, then confirmation of EBV infection should be sought by other serologic tests. A variety of antibodies directed against various EBV components can be detected by hospital, state health, or commercial laboratories. Patients with EBV mononucleosis but with negative heterophile results will have antibodies against specific EBV components.

Four different antibodies define the EBV serologic profile: IgM antibody to viral capsid antigen (VCA-IgM), IgG antibody to viral capsid antigen (VCA-IgG), IgG antibody to early antigen (anti-EA), and IgG antibody to Epstein-Barr nuclear antigens (anti-EBNA). Not all laboratories test for anti-EA, which may be

detected in 2 patterns: diffuse and restricted. The clinical implication of diffuse or restricted is not clear for mononucleosis but is used to follow some EBV-induced lymphoma patients.

These EBV-specific antibodies appear in patients who have or have had primary EBV infection. The pattern of antibody responses can help the physician in determining the relative onset of an individual’s EBV infection. In most cases an individual develops a VCA-IgM antibody response in the acute period (first 2–3 weeks) after EBV acquisition. The same is true for the VCA-IgG antibody. Although IgG antibodies to VCA persist for life, VCA-IgM tends to disappear in 2 to 3 months. Although the height of the VCA-IgG response decreases as the acute infection resolves, serial measurements of antibody titers are not clinically beneficial as a rule. The EA response peaks at 3 to 4 weeks into the illness and was initially thought to persist only for several months; therefore, in the past, it was considered a good marker for an acute or recent infection. However, recent evidence suggests that the anti-EA response may persist for years in some children and may not develop at all in others. Finally, the anti-EBNA antibody response usually appears several weeks to months after a primary infection and is therefore a marker for past or convalescent infection. Thus, anti-EBNA has to be interpreted in light of the clinical situation. Although a few children develop this response in the late stages of the acute phase of their infection, 10% to 20% may never develop detectable EBNA. In summary, children who acquire EBV infections typically develop antibodies in the same sequential pattern (Table 275-1); however, not all patients will necessarily follow the same pattern, and clinical judgment remains important in the interpretation of such findings. Additionally, interlaboratory variability in results of EBV antibody testing has been observed, making the reliability of these tests suspect in some cases. If both the heterophile test and EBV-specific serologic results are negative, then non-EBV causes for an infectious mononucleosis-like illness should be suspected.

## COMPLICATIONS AND DEATHS

Most patients who have infectious mononucleosis recover uneventfully. Serious complications, however, have resulted from this illness; death occurs in approximately

**Table 275-1** Interpretation of Epstein-Barr Virus Serology

	HETEROPHILE ANTIBODY	EPSTEIN-BARR VIRUS SPECIFIC ANTIBODIES			
		VCA-IgM	VCA-IgG	EA	EBNA
No or first week of infection	—	—	—	—	—
Acute infection	+ / —	+	+ (>1:320)	+ / —	—
Past infection	—	—	+ (1:80–1:160)	+ / —	+

Note: Other patterns may occur in an individual patient; the above profile is for a typical individual.

EA, early antigen; EBNA, Epstein-Barr nuclear antigen; VAC-IgG, IgG antibody to viral capsid antigen; VCA-IgM, IgM antibody to viral capsid antigen.

Derived from Sumaya CV, Ench Y. Epstein-Barr virus infectious mononucleosis in children. I. Clinical and general laboratory findings. *Pediatrics*. 1985;75:1003–1010.

1 in 3,000 cases. The true complication and death rates during this illness are uncertain because many reports do not include strict diagnostic criteria for infectious mononucleosis. The relative frequencies of more common complications associated with this illness, as documented in 1 large study, are listed in Table 275-2. Many other complications, representing virtually every body organ, have also been reported with this disease.

Of 20 deaths clearly associated with infectious mononucleosis in 1 series, 9 cases were of neurologic origin, 3 were caused by secondary infection, 3 by splenic rupture, 2 by hepatic failure, 1 by probable myocarditis, and 2 from an undetermined cause. Because abdominal pain is an infrequent symptom of this illness, its appearance, particularly if severe and in the left upper quadrant, should alert the physician to the possibility of impending or actual splenic rupture. Fatal cases of Reye syndrome associated with serologic evidence of EBV infection also have been reported.

**Table 275-2**      **Complications Present in 113 Children With Epstein-Barr Virus Infectious Mononucleosis**

COMPLICATION	NUMBER OF CHILDREN %

## MANAGEMENT

Because most patients who have infectious mononucleosis recover uneventfully, physicians need do little except establish the diagnosis, explain the nature of the illness, and reassure the patient and parents. No specific therapy is indicated. Patients should rest to the extent that they believe necessary. As long as the patient can consume adequate amounts of fluids and calories, hospitalization is unnecessary. To minimize the danger of splenic rupture, ambulatory patients should avoid strenuous physical exercise and contact sports for at least 1 month or until the spleen is no longer palpable. Recent guidelines from a panel of sport medicine specialists provide clarity on re-engaging in sports after mononucleosis. Patients who have late onset of the heterophil antibody response may have a prolonged convalescence.

Corticosteroids are of unproved value in treating this illness. They should not be used routinely merely to attempt to shorten patient symptoms. Most physicians believe that their use is justified in treating severe hemolytic anemia, significant airway obstruction secondary to tonsillar hypertrophy, and thrombocytopenia. However, controlled studies documenting their efficacy for these indications are lacking. Some authorities suggest using corticosteroids if neurologic involvement is significant; but again, proof of efficacy is not available. High-dose, short-term courses of steroids (dexamethasone 0.25 mg/kg every 6 hours, methylprednisolone 1 mg/kg every 6 hours, oral prednisone 40 mg/day) have been used with dramatic improvement in airway obstruction and, at times, in neurologic signs typically noted over 24 to 72 hours. The antiviral agent acyclovir has reasonable activity in high concentrations against EBV in vitro, but it has not been shown to be beneficial in a number of clinical trials that involve patients who had infectious mononucleosis. At this time, routine acyclovir use is not recommended. Several antivirals (acyclovir, ganciclovir, vidarabine) and immunomodulating agents (interferon- $\gamma$ , interferon- $\alpha$ , interleukin-2) have been used in severe EBV infections, with varying degrees of success. For lymphoproliferative diseases, a new reasonably successful approach has been the use of anti-B-cell monoclonal antibodies (eg, anti-CD22). Other novel therapeutic approaches under investigation for the treatment of EBV-associated lymphoproliferative disease include bone marrow transplantation, treatment with ex vivo expanded EBV-specific cytolytic T cells, and infusions of donor peripheral leukocytes.

In as much as the pharyngitis of infectious mononucleosis can be indistinguishable from that of group A streptococcal pharyngitis, culture or rapid antigen testing of specimens of the pharynx may be obtained. Patients who have positive results may be treated accordingly, although some may be carriers. The physician should avoid ampicillin or amoxicillin if EBV is suspected, given that these drugs induce rash in many EBV-infected school-aged children and most young adults. The ampicillin effect has not been as well demonstrated in young children with infectious mononucleosis.

Because secondary infection in typical college settings is low, and 10% of asymptomatic young adults

appear to secrete EBV in saliva, isolation of the recently diagnosed EBV patient is unnecessary. Instead, separation of drinking and eating utensils (eg, avoiding drinking from the same glass) and avoidance of activities that cause saliva exchange are all that is required.

Accounts are increasing (although still rare) of infectious mononucleosis episodes that are quite severe, are fatal, or result in significant long-lasting problems. Most of these patients had some form of immunologic abnormality, such as X-linked lymphoproliferative syndrome, renal or bone marrow transplantation, or Chédiak-Higashi syndrome, among others. The definitive management of these patients remains unclear.

### EPSTEIN-BARR VIRUS INFECTION AND CHRONIC FATIGUE SYNDROME

In the 1980s, several reports described individuals who reportedly developed a chronic EBV or mononucleosis-like syndrome following a bout of acute mononucleosis. These patients never seemed to recover completely from their acute illnesses and complained of persistent fatigue, pharyngitis, lymphadenitis, and low-grade fevers. Subsequent studies, however, demonstrated normal immune responses to EBV and clearance of the virus in these patients. These individuals today fall under the rubric of chronic fatigue syndrome, a chronic, debilitating illness characterized by extreme fatigue, neuropsychological abnormalities, and a myriad of other problems. Although many patients who have chronic fatigue syndrome date the onset of their illness to an episode of infectious mononucleosis, virologic and clinical studies have confirmed that active EBV infection is not responsible for the illness. At present, no single infectious or other cause has been identified for chronic fatigue syndrome (see Chapter 228, Chronic Fatigue Syndrome).

### EPSTEIN-BARR VIRUS-NEGATIVE INFECTIOUS MONONUCLEOSIS

Rubella, hepatitis A, toxoplasmosis, cytomegalovirus (CMV), human herpesvirus-6 and adenovirus infections, systemic lupus erythematosus, and drug reactions can produce symptoms similar to those of EBV infection. Negative EBV titers and heterophile antibody responses strongly suggest one of these other agents or conditions as the cause of the illness under consideration. In hepatitis A, in which the heterophil test can give a false-positive result, liver enzyme levels generally are much more elevated than those seen with EBV-infectious mononucleosis. Results of serologic tests for hepatitis A will be positive, as will rubella titers (virus-specific IgM and IgG) in rubella infection. CMV generally does not produce pharyngitis with CMV-induced mononucleosis. Serology can be difficult to interpret with CMV because CMV IgM can be detected in reactivation of CMV. Illnesses that mimic infectious mononucleosis but lack serologic confirmation of EBV infection should be classified as heterophile-negative infectious mononucleosis rather

than atypical mononucleosis. The cause of most of these cases remains unknown.

### EPSTEIN-BARR VIRUS INFECTION AND MALIGNANCY

B lymphocytes that contain certain forms of EBV genome can divide indefinitely and thus can potentially cause EBV-related cancers. The virus remains latent in human hosts for the remainder of the host's life. EBV will reactivate, often multiple times per year. A robust T-cell immune system is responsible for restricting growth of the EBV-infected cells and preventing evolution of cancers when reactivations occur. These observations, together with the known association of EBV and African Burkitt lymphoma and nasopharyngeal carcinoma, have shown that EBV infection is also oncogenic in the United States. Some cases of leukemia occurring shortly after the onset of infectious mononucleosis have been reported, but no other evidence exists to support it as a cause of acute leukemia. Although in the United States the association between EBV and classic Burkitt lymphoma is not as strong as in Africa, a significant number of lymphomas and lymphoproliferative lesions that contain EBV markers (including markers of viral replication) have been found in patients in the United States. The EBV genome can be detected in about 50% of Reed-Sternberg cells found in patients with the mixed cellularity form of Hodgkin lymphoma. EBV is also a known cause of nasopharyngeal cancers. EBV has thus been associated with and is thought to be an essential factor in several forms of lymphoproliferative disease. EBV has also been associated with several lymphoreticular malignancies in patients who have AIDS. These malignancies include malignant B-cell lymphoma and colonic lymphoid hyperplasia. Additionally, EBV has been associated with oral hairy leukoplakia and lymphoid interstitial pneumonitis in individuals with AIDS. EBV is also associated with lymphoproliferative disease seen in patients immunosuppressed after solid organ transplantation. This has led to development of novel approaches in which T cells are harvested and EBV-specific activity is induced in vitro. These EBV-specific T cells are then reinfused to attack the tumors. In addition, the anti-B-cell monoclonal antibodies targeting EBV-infected B-cell cancer cells have shown gratifying results.

#### WHEN TO REFER

- Hospitalization may be necessary in the presence of airway compromise, splenic rupture, neurologic complications, or severe hemolytic anemia or thrombocytopenia.
- Consultation with appropriate subspecialists for the above complications would also be warranted.

## Chapter 276

# INFLAMMATORY BOWEL DISEASE

Dana Michelle Hines Dykes, MD;  
Shehzad Ahmed Saeed, MD

### DEFINITION

Inflammatory bowel diseases (IBDs) are a group of chronic, relapsing inflammatory conditions affecting the digestive system. Inflammatory bowel disease is characterized by inflammation generally limited to the colonic mucosa in children with ulcerative colitis (UC) and discontinuous transmural intestinal inflammation in children with Crohn disease (CD). Approximately 25% of incident cases of IBD occur during childhood; the rest occur throughout adulthood, peaking in the second and third decades of life.

### EPIDEMIOLOGY

Inflammatory bowel disease affects more than 1,000,000 individuals in North America; more than 60,000 are children. Both incidence and prevalence of IBD are increasing over time, in the West and in previously low-incidence areas such as Southeast Asia and the Middle East.

### ETIOLOGY

The exact cause of IBD remains unknown, but it is speculated that it results from an aberrant immune response to gut microbiota in genetically susceptible individuals. Rapid advances in genetic testing and analyzing technologies such as genome-wide association studies have identified multiple single nucleotide polymorphisms, with the latest studies showing approximately 163 IBD-associated gene loci, of which 110 are associated with both diseases, 30 are CD

specific, and 23 UC specific. A number of environmental triggers have also been implicated, including smoking and drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs). Inflammatory bowel disease fits the model of a polygenic complex disorder with multiple potentiating triggers.

### DIAGNOSIS

#### Signs and Symptoms

Pediatric IBD may present with a variety of symptoms, including diarrhea, hematochezia, abdominal pain, fever, weight loss, and growth delay. Although diarrhea is the most common symptom and is present in 70% to 85% of children with IBD, a child's predominant complaint may be less obvious at first glance and may change depending on the child's age or the location of the disease. For example, diarrhea and abdominal pain are common to both disorders, but up to 35% of children with CD have altered growth and development, whereas children with UC may experience growth problems only 10% of the time. Bloody diarrhea occurs in most children with UC (90%), while children with CD experience this between 15% and 60% of the time. Many patients complain of pain or cramping, and sometimes the location of pain (particularly right lower-quadrant) may be confused with pain typical of appendicitis. Stooling history should be elicited for patients with concern for IBD, particularly with CD, and could be described as tenesmus, urgency, anal pain, labial pain, or other symptoms surrounding defecation. Patients may present with intestinal complications that differ by diagnosis. Children with ulcerative colitis may develop toxic megacolon, in which the colon becomes large and dilated; this is associated with hemodynamic instability, extreme pain, and decreased bowel sounds, and may lead to bowel perforation. Children with CD may develop vomiting, fever, abdominal fullness, pain related to obstruction, intra-abdominal abscess, or fistulae.

Extraintestinal symptoms are present in more than half of children with IBD, and often are present at diagnosis. These symptoms may include arthralgias or arthritis, liver disease (autoimmune hepatitis or primary sclerosing cholangitis), skin manifestations (erythema nodosum or pyoderma gangrenosum), or ocular findings such as uveitis or iritis. Aphthous ulcers in the mouth are common in CD, but other oral lesions may occur in the mouth or on the tongue and may point to deficiencies in micronutrients such as zinc or iron. Although children with CD may be more affected by growth and pubertal delay than children with UC, either condition may put them at risk for slow weight gain, growth failure, or altered bone health related to nutrition, chronic inflammation, and steroid exposure.

#### Differential Diagnosis

Diarrhea is among the most common presenting complaints among children with IBD, but, because it is a common pediatric complaint, this symptom is unreliable on its own to diagnose IBD. Initial differential diagnosis should include infectious causes of diarrhea (eg, bacteria, including *Clostridium difficile*, viruses, and parasites such as *Giardia* or *Cryptosporidium*)

because they are common in the general population. In the setting of weight loss or other concerning symptoms, causes to consider could include malabsorptive conditions such as celiac disease or pancreatic insufficiency, immune deficiency (which is often associated with diarrhea in childhood), bacterial overgrowth (particularly in the setting of previous bowel surgery where intestinal motility may be altered), or hormonal causes (rare endocrine tumors such as VIPomas, hyperthyroidism). In the absence of weight loss or other red flags, irritable bowel syndrome may also be a potential etiology for nonbloody diarrhea. Bloody diarrhea should be investigated with infectious testing, but other causes such as vascular abnormalities, cancer or polyps (rare in childhood), other inflammatory conditions such as Behçet syndrome, or toxin-mediated conditions such as NSAID exposure should also be kept in mind as possible causes.

### Diagnostic Approach

Of key importance in the diagnosis of IBD is determining which children may be evaluated as outpatients and which need to be admitted to undergo diagnostic testing. Symptoms may have been present for months prior to diagnosis, so vital signs should be obtained for all children to evaluate for volume depletion related to fluid or blood loss. History should be obtained to determine timing of diarrhea (>2 weeks may more likely be associated with IBD), whether blood is present, and whether a child is waking at night to defecate—a feature that may differentiate more benign forms of diarrhea such as irritable bowel syndrome. Patients should be examined for signs of chronic disease such as pallor, wasting, or growth problems. Abdominal examination should be performed to evaluate for the location and nature of pain and also to assess for possible complications suggestive of obstruction (distention, decreased bowel sounds), perforation (abdominal rigidity, pain, decreased bowel sounds), or areas of fullness or mass suggestive of abscess. Rectal examination (inspection and digital examination) is a critical part of the physical examination that may provide clues to underlying IBD. Patients with CD will often have anal tags, fissures, or fistulae, and unless these are actively sought out, they may be missed on simple symptom elucidation. Signs of extraintestinal manifestations such as oral lesions, erythema nodosum, or liver involvement may also be found. Testing for occult blood is also an important aspect of the physical examination. Children thought to be at risk for IBD should be referred to a gastroenterologist for appropriate diagnostic procedures, such as endoscopy, to make a formal diagnosis.

### Laboratory Findings

Initial laboratory findings in IBD may be helpful and point toward the diagnosis of this chronic inflammatory condition, but there is no single laboratory marker indicative or diagnostic for IBD. Commonly evaluated tests include inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein) and elevated acute phase reactants such as elevated white blood cell count and platelet count. For children

with chronic symptoms or bloody diarrhea, hemoglobin is often useful, as these children are likely to be anemic. Albumin may also be helpful and is a marker of malabsorption or protein losses. Unfortunately, almost 30% of patients with mild IBD may have normal ESR, hemoglobin, platelet count, and albumin, so stool biomarkers of inflammation such as fecal calprotectin may identify at-risk individuals. Fecal calprotectin is a neutrophil protein elevated in many types of intestinal inflammation, including infection, and has been shown to have up to 92% sensitivity and 76% specificity as a screening tool for IBD. Fecal calprotectin has been shown to correlate with mucosal inflammation, may predict relapse, and may be used to monitor response to medical therapies.

Biomarkers and genetic predictors for IBD may help predict disease activity over time. More than 100 genes have been identified as potential contributors to IBD, with *NOD2* among the most extensively studied as a risk factor for the development of more aggressive disease course in CD. Biomarkers typically are antibodies to microbes in the gastrointestinal tract, such as anti-neutrophil cytoplasmic antibodies, anti-*Saccharomyces cerevisiae* antibodies, and antibody to *Escherichia coli* outer membrane porin. Patterns of biomarker positivity may differ by diagnosis (UC vs CD), but may be better suited to predict risk of disease complications among children with CD. Presence or absence of biomarkers is not typically useful for diagnosis of IBD (particularly as a single test) since they may be present in the general population and are often absent in children with IBD.

### Imaging

Imaging is a necessary part of the early diagnostic workup of children with IBD and often is needed in some form after diagnosis. The type of imaging required depends on the situation and urgency. Potential reasons for imaging include categorizing disease extent, evaluating for complications, or monitoring response to treatment. Techniques employed may vary based on experience of the center and availability of technology. Basic radiographic techniques for evaluation of disease include the following:

- Plain abdominal radiograph: typically helpful for acute changes or emergencies (vomiting, acute pain, distention, concern for perforation or bowel obstruction)
- Upper gastrointestinal (GI) series with small-bowel follow-through (plain radiographs with ingested contrast being followed throughout the GI tract): widely used and well-tolerated examination used for evaluation of small bowel disease extent, particularly if there is no concern for an intra-abdominal process (abscess, stricture, fistula) or perianal disease.
- Magnetic resonance imaging (MRI) and computed tomography (CT): traditional MRI and CT are used for evaluating disease extent and providing additional benefit of intra-abdominal abscesses and fistulae identification. Enterography techniques are available employing a different oral contrast designed to distend the bowel wall as well as glucagon to change GI motility. These provide additional information about areas of narrowing or stricture

and intra-abdominal complications, and may identify other extraintestinal complications. Depending on availability, these examinations (particularly CT enterography) are thought to be the gold standard for evaluation of small bowel disease extent. Magnetic resonance imaging of the pelvis is the typical modality for evaluation of perianal disease that cannot be properly evaluated by an IBD surgeon or if complex perianal disease is suspected. Standard abdominal CT is helpful for more urgent evaluation of complications.

- **Ultrasound:** a radiation-free technique is being developed as a tool to evaluate for disease extent and intra-abdominal complications, but may be limited by operator experience and body habitus. Endoscopic ultrasound and pelvic ultrasound are available, but are more invasive and require special expertise for interpretation.

### Diagnostic Procedures

Endoscopic procedures are the main type of diagnostic procedures for IBD and are necessary to determine disease type and extent. Conventional ileocolonoscopy and microscopic examination of biopsies remain the gold standard for diagnosis of IBD. The entire colon and ileum should be examined, because visualization of the distal colon only with proctosigmoidoscopy may not give enough information to make an appropriate diagnosis. Endoscopic examination of the upper digestive tract may also help differentiate types of disease in children, but is not absolutely necessary. Biopsies during endoscopy are crucial to help classify type of disease. Subsequent endoscopies after diagnosis may be needed if a change in therapy is being considered or to examine for dysplastic changes after diagnosis. If the small intestine cannot be examined visually during upper or lower endoscopy, capsule endoscopy (use of a wireless ingested camera to visually examine the mucosa) may provide visual assessment of disease extent as an alternative to radiographic procedures, but cannot provide biopsies.

### Classification

At diagnosis, a physician must differentiate between CD and UC (or indeterminate colitis if a diagnosis is not yet available) to guide therapeutic or surgical options and possibly offer some idea about prognosis. Distinction is made by a combination of endoscopic and histologic criteria. At time of diagnosis, differentiation can sometimes be made between conditions by examining the distribution and location of disease—UC typically has continuous involvement of part of or the entire colon, while CD may be patchy and can affect any part of the luminal GI tract. However, these features may not be straightforward since UC may be associated with mild gastritis and “backwash ileitis” from adjacent inflammation of the colon, and CD may affect the colon only. Microscopic criteria such as patchy disease, granulomas, or transmural disease are associated with CD rather than UC. Crohn disease tends to be more segmental and sometimes has deep linear ulcers at diagnosis, segmental colitis, or findings of perianal disease. The presence of complications

such as stricturing disease or internal abscesses is associated with CD and not UC.

### TREATMENT APPROACH

Treating IBD depends on degree of severity, disease location, and potential complicating features such as fistulae or abscesses. In general, the goals of therapy are to provide symptom relief, minimize side effects of medications, ensure adequate growth, and maintain good quality of life. For mild disease presentations, first-line therapy would usually include aminosalicylates such as mesalamine. For disease affecting the rectosigmoid area, topical therapy such as mesalamine suppositories or enemas may be beneficial. For more moderate disease activity, corticosteroids are normally used to induce remission, but alternate therapy will be needed for maintaining remission once achieved. These maintenance medications include immunomodulators or enteral therapy. The potential side effects of immunomodulators need to be discussed and screened for at periodic intervals and include bone marrow toxicity, hepatotoxicity, and risk of malignancies. Enteral therapy is effective in inducing and maintaining remission in up to 85% of children with CD who are treated. For severe disease, step-up therapy with biologics (biologic response modifiers) is usually employed with pediatric response rates over 80%.

Drugs from different therapeutic classes may, at times, be used additively. Occasionally, for some children with complicated disease (eg, fistulizing disease, growth delay, or severe ulcerative colitis), a step-down approach with early introduction of stronger agents, such as the anti-tumor necrosis factor (TNF) agents, has been advocated to prevent progression of complications and improve outcomes.

### ONGOING CARE

#### Prevention Strategies

Children with IBD should receive all recommended childhood vaccinations, but with some potential adjustments based on medications. Patients on corticosteroid therapy may not respond to vaccinations, so they should be given before starting therapy or 3 months after they stop therapy. Children on immunosuppressive medications should not receive live-virus vaccinations, so if these medications are being considered, live-virus vaccines should be administered prior to the need for immunosuppressives. Varicella and hepatitis B may be 2 particular conditions that should be intentionally investigated prior to initiating therapy because of risk of severe disease associated with some types of treatments, particularly anti-TNF. If varicella exposure is unknown or if vaccination is uncertain, titers should be checked and vaccine administered prior to starting therapy (if appropriate for the clinical condition). Latent hepatitis B may be reactivated in the setting of anti-TNF therapy, and patients with IBD may have a lower rate of immunity to hepatitis B vaccine, so hepatitis B surface antibody and antigen should be considered before initiating these agents.

Children living with any chronic disease may struggle with coping and psychological issues surrounding

their disease. Children with IBD struggle with a variety of issues, including anxiety, depression, body image and social isolation. Children should be screened for these issues and offered access to psychologists early in the disease course, if possible. Children and families may benefit from support groups and services and should be encouraged to seek out resources even if they feel they are coping well. These resources may provide additional benefits in terms of education, development of self-management skills, and answers to common questions or concerns.

### Prognosis and Natural History

Inflammatory bowel disease does not affect overall life expectancy, but patients may have significant morbidities related to disease progression. Many children with IBD, particularly those with childhood-onset disease, may have more severe disease resulting in hospitalization or surgery. Up to 30% of children with CD and UC require surgery within the first 5 years after diagnosis. Gastrointestinal infections, particularly *Clostridium difficile* infection, are a common reason for hospitalization among children with IBD and have a high recurrence rate. Children requiring medications affecting the immune system (steroids, TNF- $\alpha$  inhibitors, or immunomodulators) have a higher rate of serious infections.

Other risks for children with IBD include nutritional and potential oncologic complications. Children with IBD have suboptimal bone health related to a variety of factors such as frequent steroids, suboptimal nutritional status, and inflammation, which place them at increased risk for osteopenia or osteoporosis, resulting in increased fractures. Vitamin deficiencies may occur in children who had bowel resections and should be monitored closely. Children with IBD, particularly with colitis, are at a 1.5- to 2-times higher risk of colorectal cancer than individuals without IBD, and patients with younger onset of disease may have an even higher risk of developing disease.

Cancer surveillance is recommended to begin at about 8 years from diagnosis and then every 1 to 3 years. Medications used for IBD may impose a slightly higher rate of skin-related cancers, so a skin examination should be performed at routine visits. Some medications used for treating IBD (particularly immune modulators) may be associated with an increased risk of lymphomas, but these risks remain small in proportion to the risk of untreated disease.

### Comanagement

In general, the approach to outpatient pediatric care for children with IBD should be similar to that for children without chronic disease, but with special attention to growth and developmental complications, and infection and malignancy risk. Children with IBD may see the GI specialist only once or twice a year, so both the GI specialist and primary care physician should comanage certain parts of every visit such as growth and development (height and weight at every visit), assessing psychological coping, and a complete physical examination. Communication between the primary care physician and GI specialist is critical, with some expectations set upfront for general pediatric care, need for GI specialist input,

monitoring for potential medication side effects (eg, bone marrow and hepatotoxicity with immunomodulators), and growth parameters. A routine physical examination should be done at every visit to assess for intestinal complications, drug toxicity, or malignancy (particularly of the skin and lymphatic systems). Routine vaccinations should be maintained by the general pediatrician if possible, although vaccination for influenza or vaccine boosters for nonresponders (such as hepatitis B) can be given whenever the child is medically able to receive them in an effort to avoid return visits. Every effort should be made to return the child to the primary care physician for coordination of services, particularly if the child sees multiple providers for other conditions. The GI specialist should remain available for GI-related issues (weight loss, vomiting or diarrhea, change in abdominal pain, ongoing fever, or concern for flare). A document (either clinic notes or a medical passport) may help detail the ongoing issues and facilitate communication.

### WHEN TO REFER

“Red flags” that would warrant a referral to a GI specialist include historical factors such as

- Poor growth or weight loss
- Persistent rectal bleeding with no obvious source on examination
- Recurrent perirectal abscess

Laboratory values obtained during evaluation that may warrant a referral to GI specialist include

- Microcytic anemia
- Elevated acute phase reactants
- Hypoalbuminemia
- Elevated fecal markers of inflammation (fecal calprotectin, lactoferrin)

### WHEN TO ADMIT

- Recurrent fevers or concerns for abscess
- Persistent vomiting or bloody diarrhea suggesting obstruction, dehydration, or need for blood transfusion
- Severe abdominal pain and distention suggesting “toxic megacolon” (severely dilated colon)
- Significant malnutrition for nutritional rehabilitation with oral supplementation or intravenous hyperalimentation

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 277

## INSECT BITES AND INFESTATIONS

David H. Stein, MD, MPH; Nancy K. Barnett, MD

### INSECT BITES

Insect bites and stings are an expected, frequent consequence of childhood activities but can cause serious illness and threaten life in susceptible individuals. Insects and arachnids (mites, ticks, and spiders) can produce anaphylaxis or act as vectors of serious or fatal disease, including viral encephalitis and malaria. Worldwide, malaria and other insect-carried diseases are among the most common causes of serious childhood morbidity and death. In the United States, ticks are the most common insect vectors of disease, spreading Lyme disease and other infections, which are discussed elsewhere. The prevalence of harmful insect species varies over time; for example, there is a current widespread increase in bedbug infestations, which have now affected numerous public buildings, including both acute care and chronic care health facilities in many US cities. (Figure 277-1). The Centers for Disease Control and Prevention (CDC) offer abundant current information on vector-borne diseases ([www.cdc.gov/nceid/dvbd](http://www.cdc.gov/nceid/dvbd)).

### Patient Evaluation

A history of being bitten or stung, or simply of localized itch, burning, or pain, may be present. On examination of the skin, insect or arachnid bites appear as discrete, erythematous, or flesh-colored papules, nodules, wheals, vesicles, or bullae, which sometimes display pigment alteration and are usually pruritic (Figure 277-2). Bites are most commonly found on surfaces left uncovered by clothing and may be clustered, or in a linear, arc-like or other pattern,

**Figure 277-1** Bed bug. Note the flattened, oval body of this bug, which was brought in to the clinic by the patient's mother. (Krowchuk DP, Mancini AJ, eds. *Pediatric Dermatology: A Quick Reference Guide*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012.)

**Figure 277-2** Mite bites. Multiple, clustered, edematous red papules and plaques. (Krowchuk DP, Mancini AJ, eds. *Pediatric Dermatology: A Quick Reference Guide*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012.)

especially when a crawling insect bites (Figure 277-3). Some bites have central puncture marks or vesicles; others are capped by pustules or by hemorrhagic or serous crusts. On occasion a whole or partial insect body may remain attached to the skin, especially in the

**Figure 277-3** Flea bites. Note the *breakfast, lunch, and dinner* sign. (Paller AS, Mancini AJ. Hurwitz Clinical Pediatric Dermatology: A Textbook of Skin Disorders of Childhood and Adolescence. 4th ed. Philadelphia, PA; Elsevier Saunders; 2011, with permission from Elsevier.)

case of a tick bite. Careful examination with magnification may be indicated to preclude insect parts remaining in the skin, especially from tick bites. Excoriations or changes consistent with dermatitis (reddish, ill-defined areas with an altered surface texture and often scaling or scale-crust) are common. Larger nodules or blisters may appear as more robust reactions to insect- or arachnid-associated toxins, particularly in those with prior exposure (sensitization) to insect antigens. Immediate (anaphylactic) reaction in those with or without known prior exposure can be life-threatening. Multicentimeter plaques, sometimes referred to as *large local reactions*, may be severe, reaching more than 10 cm in 1 or 2 days after a bite or sting. Such reactions may increase the risk for more severe outcomes upon additional antigen exposure from bites.

Additional complications of bites include localized infection or more widespread dermatitis (eczematous dermatitis); other localized or widespread hypersensitivity reactions, including papular urticaria; and other systemic immune reactions. More acute or widespread complications can also result from the application of topical remedies, such as topical antibiotics, especially neomycin, or other easily available and advertised products, thus causing irritant or allergic contact dermatitis and greatly increasing itch or leading to ever more acute clinical findings.

Systemic infections, such as viral encephalitis or tickborne disease, should be considered as potential

complications necessitating more thorough follow-up. Bacterial infection of bites can lead to cellulitis or a multitude of toxin-induced or immune-mediated complications such as nephritis. Papular urticaria is a common hypersensitivity reaction to insect bites and consists of recurrent crops of urticarial (hive-like) papules, nodules, or wheals that may be either new areas or reactivated old bites. Papular urticaria occurs in sensitized individuals and can last days, weeks, or months, plaguing the patient with profound itch and areas of disrupted skin barrier function, which are susceptible to bacterial infection, especially if the papules are repeatedly scratched or otherwise traumatized. Scratching can also leave scarring or postinflammatory pigment change, most often as hyperpigmentation. The differential diagnosis of insect or arthropod bites includes papules from various eczematous conditions (eczematous dermatitis) or follicular inflammation (folliculitis) as well as inflamed viral molluscum, other viral infections, and reactions to foreign material deposited in the skin.

### Treatment of Insect Bites

Bites from insects should ideally be prevented primarily by protecting as much of the body as possible with clothing or bed nets (especially for infants) and by judicious, careful use of repellents. Highly efficacious repellents include Picaridin and DEET (DEET is known, worldwide, by more than 1 chemical name, including N,N-diethyl-m-toluamide). Picaridin may be the safer of the 2 widely available repellents (see [www.epa.gov/opp00001/chem\\_search/reg\\_actions/registration/fs\\_PC-070705\\_01-May-05.pdf](http://www.epa.gov/opp00001/chem_search/reg_actions/registration/fs_PC-070705_01-May-05.pdf)). The use of oils of lemon eucalyptus is widely recommended and likely efficacious, but numerous preparations offered through many suppliers may lack standardization or comparable potency among products. Any of these repellents can be applied to exposed clothing or to skin in small amounts with care, avoiding children's hands, eyes, and mouth areas. Repellents are best washed off when no longer needed to reduce skin irritation and potential for toxicity. DEET is usually safe to use intermittently and in moderation at concentrations of 30% or less in children older than 2 months, but toxicity has been reported, and current recommendations of the American Academy of Pediatrics, CDC, or Environmental Protection Agency should be consulted. Susceptibility to mosquito bites may be decreased by avoiding other potential attractants, such as bright clothing. When available, the use of bed nets impregnated with repellents may be protective during rest periods.

Those at risk for anaphylaxis after being bitten or stung should be treated immediately with epinephrine and should always have epinephrine autoinjectors immediately available. Ice or cold packs should be applied to bites as quickly as feasible to reduce itch and inflammation because of hypersensitivity, inflammatory reaction, or potential diffusion of insect toxins. Topical antipruritic products such as plain calamine may be soothing. Low- to mid-potency topical corticosteroid creams, such as 2.5% hydrocortisone or 0.025% to 0.1% triamcinolone, reduce inflammation and itch and are the primary treatment, along with

cold packs and oral  $H_1$  blocking agents. Topical antihistamines and topical antibiotics should always be avoided; they are ineffective and may cause allergic contact dermatitis. Hydrocortisone at 1% concentration has little efficacy, owing to the depth of insect bite reactions in skin. In rare cases, for extensive bites with ensuing hypersensitivity manifesting as widespread papules, a limited 1- to 2-week or shorter course of oral systemic steroid at approximately 0.5 mg/kg of prednisone or equivalent might be considered. Topical corticosteroid therapy should be started at the same time to reduce chances of a rebound phenomenon upon cessation of oral corticosteroid use.

## PEDICULOSIS

Human lice are obligate ectoparasites that create pruritic dermatoses after their bites puncture the skin and inject saliva, which incites inflammation and sometimes hypersensitivity. Lice can transmit human diseases, including typhus, and are spread primarily by close human contact but also by fomites; for example, the body louse is primarily spread in clothing. Outbreaks of head lice occur among groups of all types and ages that spend long periods in close contact but especially among school-aged children. Lice infestation of the scalp is called *pediculosis capitis* (Figure 277-4); infestation of the eyelashes is known as *pediculosis palpebrum*; and pubic area involvement is called *pediculosis pubis*. In each situation, lice live just above the skin, often on hair shafts, but feed from the underlying skin surface. *Pediculosis corporis* describes an infestation of the limbs and trunk with lice living in clothing or on bedding, rather than on terminal (mature and pigmented) hair, as lice do in the other types of infestation noted.

On careful examination with the eye or low magnification (3× to 10×), the grayish, crawling, 6-legged louse is seen near the skin in areas of thick terminal hair growth or on fomites. Louse egg or larval sheaths, called *nits*, appear as minute, white-gray, firmly fixed attachments to hair shafts. In the absence of visible lice, nits may not be diagnostic of active infestation. Importantly, several types of debris or small masses of dead skin from scalp inflammation or infection, such as fungal infection, may be easily mistaken for nits. Specialized combs are often helpful in finding lice or nits when they are challenging to find. Pruritus, sometimes accompanied by erythematous papules, 1 to 3 mm in diameter, caused by bites of the head louse, may be noted around the nape of the neck and the hairline or on other areas of skin. Cervical adenopathy and occasionally urticarial-like changes or similar involvement of other body areas may be present. Family members should also be examined, especially if combs, towels, and other personal items are shared. *Pediculosis pubis* is often sexually transmitted, and affected individuals may have other sexually transmitted infections.

*Pediculosis corporis* should be suspected when widespread pruritus is present along with erythematous papules and signs of scratching, especially on covered or hairy body areas. Excoriations, impetiginization, eczematous changes, overt bacterial or other infection, and pigment changes are common. Body

**Figure 277-4** Head lice. Note numerous nits attached to hair shafts. (Krowchuk DP, Mancini AJ, eds. *Pediatric Dermatology: A Quick Reference Guide*. 2nd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012.)

lice and nits may be seen in the seams of clothing or on bedding or other fomites.

## Treatment of Pediculosis

For head lice or pubic lice, repeated physical removal of lice and nits is essential. Only when needed, and as an adjunct to careful physical removal, should permethrin, dimeticone, or pyrethrins be tried. The use of chemicals is to be avoided in infants and during pregnancy or while nursing. Resistance of lice to chemical agents is greatly increasing, and some medications may be completely ineffective. Mechanical means of removal, especially using surface agents such as silicone, is increasingly useful, as are other “physically active” compounds. Retreatment is usually necessary about 1 week after the first application to kill lice that have hatched from viable nits that were not killed initially. Malathion used as a 0.5% solution must be left on for 8 to 12 hours and is flammable. Dimethicone 4% may also be effective, even as a single application. Insecticides, especially lindane ( $\gamma$ -benzene hexachloride [GBH]), are highly toxic and less effective compared with other measures and should be avoided. Two doses of oral ivermectin given at least 7 days apart have been shown to be effective in the treatment of several kinds of lice infestation, although this application is an off-label use. Chemical treatments for pediculosis, especially those containing lindane, should not be used for infants and for pregnant or nursing women.

Clothing, bedding, combs, towels, and other items used by lice-infested persons should be washed in hot water of at least 149°F (65°C). The most effective treatment for body lice is the total-body application of 5% permethrin cream (Elimite) for 8 to 14 hours. Permethrin 1% should never be used because of resistance. Simultaneously, all potentially infested clothing must be treated with wet or dry heat (or both) at a minimum of 149°F (65°C) preferably for at least 30 minutes. The use of multiple modes of treatment with differing treatment methods may be needed. A vinegar rinse may help remove stubborn nits. All clothing, stuffed

animals, comforters, and other items that cannot be washed or dry-cleaned should be stored in a plastic bag and sealed for 2 weeks or more. No-nit policies aimed at excluding children from school are ineffective. Overlooking nits is easy, and such policies penalize children excessively by causing missed school days. The American Academy of Pediatrics recommends avoiding such policies.

Pruritus may continue for 2 weeks or more after treatment, perhaps because of continued presence of dead lice or related antigens. In addition, topical agents may cause irritant dermatitis. Patients should be advised that they might continue to itch so that they do not over-treat themselves through excessive repeated applications. Oral antipruritic agents, such as mild antihistamines ( $H_1$  blockers), soothing bland lotions, and topical steroids, can help control pruritus. Additional current information for patients and providers is available at [www.cdc.gov/parasites/lice/index.html](http://www.cdc.gov/parasites/lice/index.html).

Pediculosis palpebrum can be treated by applying plain petrolatum to the eyelashes 4 to 5 times daily. Treatment is required for approximately 8 to 10 days, and a fine comb should be used daily to remove lice and nits from the eyelashes. Other infested body areas should be treated simultaneously. If this method fails, then physostigmine 0.25% may be similarly applied to eyelashes and is usually curative in 3 or 4 days but may interfere with vision.

Pediculosis pubis is also treated with measures to physically remove lice and with permethrin or pyrethrins, at 5% concentration. Nonprescription pyrethrin preparations are probably less effective, and optimal lengths of application are shortest with 5% permethrins; but here, too, resistance to chemical agents continues to increase, and physical removal of nits and lice should also be undertaken.

## SCABIES

Infestation with the mite *Sarcoptes scabiei hominis* causes scabies, a common and extremely pruritic dermatosis that usually affects several regions of the skin in a characteristic distribution. Confirmation of scabies infestation is sometimes possible, as described later, but is *often unobtainable* because of an absence of any adequately specific or sensitive diagnostic test. It is likely that children are affected more often than adults owing to frequent close contact with other children, especially in schools, child care, or other institutional settings.

Scabies is usually spread by close personal contact, most often by skin-to-skin contact, such as through individuals sleeping in the same bed or holding an affected child close to one's body, as well as during close play among children. It has been estimated by various researchers that 20 to 30 minutes of close contact is optimum for transmission, but shorter contact may often be sufficient. After *initial* infestation, clinical signs develop after about 2 to 6 weeks; overt clinical findings follow the initial burrowing of scabies mites into the epidermis, with subsequent development of delayed (cell-mediated) host immunity. New infection of a previously immune host can result in itching and rash in as little as 1 to 3 days. Acquisition of scabies from fomites is thought to be much less common

because mites generally survive no more than 3 days off of a host, even in ideal conditions of high humidity. Nonhuman varieties of scabies mites, such as those that infest dogs or larger mammals, lead only to self-limited skin changes on human skin; this is because scabies mites are highly specific to a host species and mites fail to effectively reproduce on species other than their primary host species.

In many instances, history will reveal that several people in a dwelling have a rash and widespread persistent itching. Clinical diagnosis of scabies should be based primarily on the distribution of erythematous papules, nodules, or other inflammatory changes and, where present, more specific findings, such as burrows. Examination of close contacts with suggestive skin findings is often helpful for confirmation. Burrows, seen as fine (1- to 2-mm wide) flesh-colored to slightly pink, minimally raised, linear or serpiginous plaques are created by female mites and may help to establish the diagnosis; however, burrows are generally not obvious and are present in fewer than one-half of all patients. Burrows are most often found in the finger webs or on the wrist area but are frequently disguised by excoriations, eczematous reactions, or superimposed infection. Most commonly, papules, nodules, eczematous changes (eczematous dermatitis), or excoriations are found on the digital web spaces, the extensor surface of the elbows and knees, and the flexor aspect of the wrists, as well as the axillary, upper trunk, waist, and groin area. Only in infants is involvement of the palms and soles, especially with vesicles, common, as are findings on the face and head. In patients who are immune suppressed for any reason or who cannot effectively scratch, extensive and widespread urticarial, eczematous, or crusted changes can mimic many other inflammatory skin diseases, especially arthropod bites or other forms of eczematous dermatitis. Widespread eczematous infestation with numerous mites is sometimes called *crusted scabies* or *Norwegian scabies*.

Confirmatory ova, mites, or feces are often difficult to visualize because most involved areas of skin do not contain mites or ova. Light microscopy of scrapings of the bottom of burrows or papules from distal body sites after a drop of mineral oil is placed on the skin and examined under less than 40 $\times$  magnification can be confirmatory, especially if mites, with their characteristic anatomy, are seen. The clinical differential diagnosis for scabies includes insect bites and papular urticaria, as discussed earlier, and various forms of eczematous dermatitis and folliculitis. Papules, pustules, vesicles, eczematous dermatitis, and even urticarial plaques can occur in sarcoptic infestation and justify the reputation of scabies as a great masquerader. In the setting of worsening or persistent widespread pruritus with inflammatory skin changes, a diagnosis of scabies must be considered, especially if close contacts are also itching. The distribution of skin changes over the body, rather than the detailed appearance of each area, is usually the best clue to the diagnosis.

## Treatment of Scabies

Family members, sexual partners, and other close contacts of index cases, especially those having

skin-to-skin contact, should always be simultaneously treated because they are often asymptomatic carriers. Carriage and spread of scabies mites can result from delays of up to several weeks before clinical changes appear (see earlier discussion), if such changes do eventually appear at all. Not all individuals develop hypersensitivity findings that are clinically evident, and failure to examine or treat close contacts is likely to result in transmission to others and even repeated infestation of the originally treated individuals. Animals, such as pets, do not need to be treated in conjunction with scabies in humans, for the reasons noted previously. The treatment of choice for scabies is the very thorough application of 5% permethrin to the entire body, and the simultaneous treatment of all close contacts, such as those living in the same household, who are likely to have had skin-to-skin or other very close contact with the patient. Repeat application about 7 to 10 days later is sometimes justified, especially if there are concerns over compliance with treatment or potentially untreated contacts. Because the most common rash of scabies—excluding “crusted” scabies—are largely attributable to cell-mediated immunity, full resolution of the rash can take weeks. Additional treatment for itch, with mid-potency topical steroid (0.025% to 0.1% triamcinolone) and oral antihistamines such as hydroxyzine or cetirizine, should be offered.

Oral ivermectin offers the best alternative to topical permethrin, including much better patient adherence than topical treatment, but with oral ivermectin, 2 separate doses spaced 7 to 14 days apart are needed because of failures of this widely used alternative to eradicate unhatched ova in skin. Published clinical treatment data in young children are very limited, but the response to treatment and severity of infestation should determine the need for repeated treatment. Diagnosis and various treatments have recently been more extensively compared (see Suggested Readings).

Lindane and other insecticides should be avoided because they are considerably less effective and have a meaningful risk for adverse reactions, especially with repeated treatment. Any topical treatment can cause an irritant dermatitis, but lindane is most likely to do so. Current literature lacks population-based studies adequately demonstrating the efficacy of malathion, another toxic organophosphate insecticide. Crotamiton 10% (Eurax) is probably less efficacious, must be applied at least twice, and is used less frequently in the United States. Benzyl benzoate is used widely as an inexpensive emulsion and is sometimes recommended by the World Health Organization, although it is not generally available in the United States.

Epidemiologic studies have demonstrated a high rate of spread within families and between multiple individuals sleeping in the same bed. Therefore, bed linens, clothing, and towels should always be washed in hot water immediately after the simultaneous treatment of all individuals in the same household or facility. Fomites or nonwashable clothes, worn during the days before treatment, may be secured in plastic bags, dry-cleaned, or wrapped for 3 days to remove any risk for contagion.

Although pruritus and rash may persist for at least 2 to 8 weeks or longer after successful eradication of an infestation because of continued hypersensitivity

and traces of antigen in skin, repeat treatment to kill mites should be undertaken only when continued infestation with live mites is highly suspected. Some individuals develop red to purple discrete nodules up to 2 cm in diameter on surfaces usually covered by clothing, particularly on the genitals or around the axilla, and these nodules may persist for many months. These *nodular scabies* or *post-scabetic nodules* are thought to represent a robust hypersensitivity reaction. These nodules heal slowly but usually respond to topical or intralesional injections of corticosteroids for itch. Additional precautions regarding chemical treatments outlined previously for pediculosis also apply for scabies.

Complications of scabies, pediculosis, or other infestations, such as superficial or deeper bacterial infection (cellulitis), sometimes with toxin-producing bacterial strains, may necessitate systemic treatment, especially in young or immune-suppressed children. Attention must be given to the potential for long-term sequela of bacterial infection, such as nephritis.

### WHEN TO REFER

- The patient may be referred to allergists if the patient develops severe allergic reaction to insect bites, especially repeatedly, or if hymenoptera allergy is suspected.
- Dermatology referral is appropriate for suspected scabies, especially if there is risk for contagion within an institutional setting like a school or hospital or if suspected infestation is unresponsive to treatment and for other persistent itchy eruptions.

### WHEN TO ADMIT

- If the patient has severe systemic allergic reactions, such as anaphylaxis, to insect bites
- If the patient needs intravenous antibiotics to treat secondary bacterial infection, cellulitis, or systemic infection
- If the patient develops acute noninfectious complications such as acute postinfectious glomerulonephritis and hypertension
- If the patient is suspected of having contracted viral meningitis or other severe or systemic illness through insect bites

## Chapter 278

## INTELLECTUAL DISABILITY

Randall A. Phelps, MD, PhD; William I. Cohen, MD<sup>†</sup>

### DEFINITIONS

More than 50 years ago, the term *mental retardation* replaced terms such as idiot, imbecile, and moron as the descriptor of choice to describe intellectual disability. Because the term mental retardation has now acquired a pejorative connotation, in 2006, the membership of the American Association on Mental Retardation voted to change its name to the American Association on Intellectual and Developmental Disabilities (AAIDD). In

2010, the US Congress followed suit and passed Rosa's Law, making "intellectual disability" the new legal definition for the diagnosis formerly known as "mental retardation." In 2013, the American Psychiatric Association published the *Diagnostic and Statistical Manual, Fifth Edition (DSM-5)*, also changing the diagnosis to ID (Intellectual Developmental Disorder). Therefore, primary care physicians, and others, should now use the term *intellectual disability* (ID) to assist their patients in obtaining appropriate supports.

In 2002, the AAIDD published 5 important elements to serve as guidelines for the accurate use of the term *intellectual disability*.

1. The level of functioning of individuals should be considered within their particular social and cultural context.
2. Any assessment of cognitive and adaptive ability should take into account communication, as well as sensory, motor, and behavioral functioning.
3. An individual's strengths must be emphasized in assessments and included in support plans.
4. The purpose of assessing limitations is to guide the development of appropriate supports for the individual in question.
5. The provision of individualized supports is expected to improve functioning significantly.

Implicit in these guidelines is the understanding that, although many cognitive and adaptive impairments are not reversible, ID can be ameliorated by environmental modifications and supports.

Much confusion exists about a variety of terms used to describe children who are not developing as expected. One commonly used term is *developmental delay*, which reflects functioning significantly behind expectations for chronologic age in a particular developmental domain (eg, gross motor, fine motor, cognition, communication). Some children experience this developmental delay in a single domain, whereas others have delays in multiple or all domains. This term is often perceived by parents and laypeople to suggest that the child will, at some time, make up the delay, as would a delayed train that finally arrives at a destination. Such catch-up frequently does occur in the case of delays in isolated domains (eg, in expressive language). On the other hand, clearly, the child who is delayed in all domains, although frequently described as having *global developmental delay*, is less likely to catch up. This situation is particularly true the greater the magnitude of the delay. In general, professionals are hesitant to describe these children as having ID until they are approximately at the age of school entry. At a practical level, this hesitation allows parents to focus on interventions that maximize the child's potential while minimizing the focus on what the child cannot accomplish. Furthermore, this term is less difficult to use by physicians and less difficult to hear by families. On the other hand, professionals and laypeople alike often continue to use the term *developmental delay* far beyond the time when there is any uncertainty in diagnosis, well into the school years, and defer the use of "intellectual disability" excessively.

The AAIDD defines ID as significant impairments in cognitive functioning and in adaptive behavior, which

<sup>†</sup>Deceased

develop before age 18 years (Box 278-1). Many professionals think that any child with cognitive impairment has ID. Given that the definition of ID includes both cognitive and adaptive impairment as essential criteria, clarifying the differences here is important. *Cognitive impairment* is defined as performance in the abnormally low range on standard assessments of intelligence. The *intelligence quotient* (IQ) is defined by a mean of 100, with standard deviation of 15. Cognitive impairment is also defined as an IQ 2 or more standard deviations below the mean. Furthermore, cognitive impairment implies significantly low scores in all domains of intelligence testing. Widely discrepant scores in various domains (eg, a verbal IQ in the normal range and a nonverbal score in the range of impairment) would be best defined as a learning disability, not as ID. Adaptive impairment is defined by functioning in the abnormally low range (more than 2 standard deviations below the mean) on formal measures of adaptive functioning, such as the Vineland Adaptive Behavior Scales. Adaptive skills include domains such as communication, self-care, home living, social or interpersonal skills, ability to use community resources, self-direction, functional academic skills, work, leisure, health, and safety.

### BOX 278-1 Criteria for Diagnosis of Intellectual Disability

1. Cognitive impairment is defined as an IQ 2 or more standard deviations of 15 below a mean of 100 ( $\text{IQ} \leq 70$ ).
2. Adaptive impairment (adaptive skills include domains such as communication, self-care, home living, social or interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety) is identified by functioning more than 2 standard deviations below the mean in these areas (as measured by formal testing of adaptive functioning, such as the Vineland Adaptive Behavior Scales).
3. Children with intellectual disability experience the onset of cognitive and adaptive impairment during the developmental period (usually <18 years of age). Onset of cognitive and adaptive impairment after the developmental period would be referred to by etiology, for example, as traumatic brain injury.

## CLASSIFICATION OF INTELLECTUAL DISABILITY

ID is traditionally subdivided by level of functioning into mild, moderate, severe, and profound. The purpose of such subdivisions should be to identify the level of support that will help that individual function best in society. Table 278-1 summarizes these levels with respect to estimated IQ, expected academic achievement by age 18 years, and anticipated level of recommended support. Adults with mild ID generally function well independently and are able to work in competitive employment and manage domestic affairs adequately. However, individuals with mild ID may have difficulty with stressful situations (eg, following a physician's recommendations). For this reason, individuals with mild ID usually benefit from the intermittent support of a care coordinator. Most adults with moderate ID are able to work in the community, but often require ongoing job coaching, particularly to cope with any changes in routine. In addition, adults with moderate ID are typically able to manage many aspects of their domestic life, such as hygiene and taking public transportation, but require some assistance with daily living. Adults with severe or profound ID are typically unable to work in the community and often require significant daily assistance with many aspects of their domestic life.

## COMMUNICATING WITH FAMILIES

Communicating with families and patients about a diagnosis of ID is challenging. Thoughtful communication is essential in helping families acknowledge a diagnosis that is difficult to accept and readying the family to access important services. Thoughtful communication requires careful and specific use of diagnostic labels and the consistent use of person-first language. To state the impairment first, as in *the intellectually disabled child*, implies that the disability is the most salient characteristic of the child. Using the term *child with an intellectual disability* is preferable. Sensitive use of language demonstrates respect to patients with intellectual disabilities and compassion for their families. The cases presented in this chapter demonstrate that the careful attention to these subtle language differences can promote emotional healing and acceptance despite the inability to cure.

**Table 278-1** Levels of Intellectual Disability

LEVEL	CORRESPONDING IQ	EXPECTED ACADEMIC ACHIEVEMENT BY AGE 18 YEARS	SUPPORT LEVEL
Mild	55–70	Fifth-grade academics	Intermittent
Moderate	40–55	Second-grade academics	Limited
Severe	25–40	Preschool academics	Extensive
Profound	<25		Pervasive

## DIFFERENTIAL DIAGNOSIS AND MANAGEMENT

Given the long-standing history of conflating mental illness and ID, it is important to clarify that the diagnosis of ID does not necessarily imply any specific behavioral disorders. In other words, most children with ID do not have significant or atypical behavior problems. However, behavioral problems and psychiatric disorders may occur at a higher rate among individuals with ID compared with the general population. Several behavioral symptoms that have often been associated with ID, such as irritability, aggression, and self-injury, are worthy of mention. These symptoms are also often seen in autism, which is a common comorbidity of ID. Autism does occur at a higher rate in individuals with ID, and a diagnosis of autism would prompt differences in management from ID alone. For this reason, specialists strongly recommend that the diagnosis of autism be considered, particularly in the face of characteristic symptoms. Also important to note is that such symptoms as irritability and aggression have long been seen as intrinsic features of ID, to the disservice of individuals with this diagnosis. In other words, the presence of ID has often precluded and continues to preclude more meticulous investigation into the cause of such behavioral symptoms. Frequently, irritability and aggression may be symptoms of psychiatric illness, such as depression or anxiety. Self-injury may be a sign of physical illness; for example, hitting the chest may be an indication of undiagnosed gastroesophageal reflux. Apparent hypersexuality, such as dropping the pants in public, may be a manifestation of an uncomfortable erection in the context of inadequate sexuality education. As illustrated in some of the cases presented here, avoiding diagnostic overshadowing or attributing all symptoms to ID is important.

Four cases are presented to illustrate the diagnosis and management of ID, learning disability, and global developmental delay.

### Case 1

*Jenny Miller, a 6-year-old girl, is accompanied by her parents to your office for a discussion about recent recommendations made by personnel at Jenny's school. Jenny has a history of global developmental delay. She has been attending a developmental preschool and has been receiving private speech therapy to supplement her Individualized Education Program (IEP) since she was 3 years old. Mr and Mrs Miller are very upset about the prekindergarten assessment report that they just received. The report states that Jenny has "mild mental retardation" and recommends learning support placement in kindergarten. Mr Miller explains that the school psychologist told them that he was giving Jenny this label so that she could access special education services. Mr Miller takes this statement as evidence that the psychologist is stretching the criteria for this purpose and questions whether the services are worth a label that will follow Jenny for life.*

*You review the evaluation report. On the Wechsler Intelligence Scale for Children (WISC-IV, an IQ test), Jenny received a verbal IQ of 67 and a performance IQ*

*of 64. The full-scale IQ is reported as 63. On the Bracken Basic Concept Scale, a measure of early childhood academic achievement, she received a standardized score of 68. On the Adaptive Behavior Composite of the Vineland Adaptive Behavior Scales, Jenny received a standard score of 55.*

*On physical examination, Jenny is at the 50th percentile for height and weight. During the examination, Jenny is able to recite some of the alphabet by rote, but she has poor articulation and does not recognize her letters. She can count to 5, but incorrectly names the number of fingers you hold up. When you ask her to place the stethoscope on her heart, she places it on her belly. She is unable to dress herself after the examination and turns to her parents for help.*

*After the examination, Mr and Mrs Miller tell you that, instead of allowing Jenny to be placed in special education, they are thinking about keeping Jenny in preschool 1 more year. This way, they hope she can catch up and enter mainstream kindergarten the following year. They ask for your advice about this plan.*

### Case 1 Discussion

Jenny fulfills all 3 of the diagnostic criteria for ID (see Box 278-1). First, intelligence testing estimates her cognitive abilities to be more than 2 standard deviations below the mean. Second, Jenny also has had formal assessment of adaptive skills, with a reported score on the adaptive scale of more than 2 standard deviations below the mean. In corroboration of the formal measures, the physician also has the opportunity to observe in the office pronounced delays in academic skills and communication, a notably small fund of knowledge, and significant difficulties with self-care, such as dressing. Third, of course, Jenny qualifies for the final criterion, being 6 years of age. The school psychologist's use of the term *mental retardation* is inappropriate here, given that this term has now been replaced by *intellectual disability* as the currently accepted legal term. Unfortunately, as of this writing, more than 4 years after the passage of Rosa's Law, the term *mental retardation* is still being used by professionals and is still encountered in various paperwork, such as IEPs, in violation of Rosa's Law.

The questions Mr and Mrs Miller pose raise several important issues. When Jenny's parents express their concern about giving her a label, they are likely expressing their sadness about a diagnosis, which they fear and do not want. In coming to the physician for a second opinion, they are searching for a more palatable diagnosis. This delicate situation calls for a gentle, compassionate, and honest approach. Jenny will benefit from the services that can be provided by the diagnosis of ID. Holding this 6-year-old child back in preschool 1 more year would not address Jenny's learning needs, and the parents would face the same difficult situation the following year. Therefore, the best way to support Jenny's development and learning is to respectfully counsel that, as a professional opinion, Jenny will not likely make sufficient progress without adequate learning support services.

Equally important is the way in which this advice is given. Mr and Mrs Miller may seem to be naive or to be in denial. Actually, they are afraid to accept special

education and its implications and are hoping to defer the inevitable for another year. Therefore, in giving this advice, acknowledging that Mr and Mrs Miller are mourning for the loss of their idealized child is important. Nevertheless, acknowledging Jenny's educational needs now rather than deferring the inevitable for another year would be best. Although the school psychologist attempted to soften the blow by stating that the label was being used to procure services, this approach resulted in confusion for the family. In fact, the psychologist was accurately reflecting Jenny's abilities and leading the family to an appropriate educational placement.

A somewhat different approach from the psychologist would include an effort to (1) avoid use of the term *mental retardation*, (2) dispel myths about the meaning of ID, (3) be straightforward that the diagnosis of ID is justified and that it is the currently accepted legal and educational term, and (4) actively empathize with the family's distress. To dispel myths, a helpful approach would be to start by asking, "What does ID mean to you?" For many families, hearing "mental retardation" conjures up images of common syndromes associated with mental retardation, such as Down syndrome. The use of the term *ID* does help to resolve such confusion. However, even when specific syndromes do not come to mind, many parents may believe that a child with ID would be unable to learn. This belief understandably contributes to confusion for parents such as the Millers, whose daughter has mild impairments. In such cases, the professional needs to explain that individuals with mild ID often do develop functional literacy and some arithmetic proficiency. It is comforting to parents to hear that "developmental disabilities" or "brokerage supports" exist in most communities, which can help young adults with intellectual disabilities obtain supported employment and living situations. Also, it should be noted here that children with even more severe forms of ID have some capacity to learn.

## Case 2

*Your office is the medical home for Max Smith, a 14-year-old boy with a history of diabetes and ID. Max is accompanied by his mother today for a school physical examination before starting high school. On the subject of school, Mrs Smith mentions that "Max had a difficult school year, with his grandpa passing away and his parents finalizing their divorce last fall." Max has an IEP. He has been receiving learning support for all of his core academic courses and has been in mainstream classes for his electives.*

*Max's most recent psychoeducational assessment was performed 2 years ago. The evaluation report states that Max has a verbal IQ of 67, a performance IQ of 62, and a full-scale IQ of 66 on the WISC-IV. On the Weschler Individual Achievement Test-III, an academic skills assessment test, Max's standard scores ranged from the high 50s to the low 70s. On the Adaptive Behavior Composite of the Vineland Adaptive Behavior Scales, Max received a standard score of 68. The evaluation report notes that Max is consistently described by his teachers as "good-natured" and that he "tries to follow directions and is friendly."*

*School reports from the last year note that Max has become increasingly withdrawn, disorganized, and irritable. Mrs Smith reports that when she asked the school counselor about Max's declining school performance, the counselor noted that, "most kids with ID have the same problem when they enter high school—they start to struggle even with the learning support curriculum and often become withdrawn as they realize that they 'don't fit in.'"*

*During the appointment, Max is quiet and withdrawn. His answers to your questions are appropriate, though somewhat concrete. Mrs Smith tells you that, citing Max's current difficulties, the school counselor recommended placing Max in a self-contained life skills classroom. She asks for your opinion about this recommendation.*

## Case 2 Discussion

Max has a history of mild ID, with a relatively acute onset of academic decline. His most recent psychoeducational data—with cognitive, academic, and adaptive testing 2 or more standard deviations below the mean—support the diagnosis of ID. Adolescents with intellectual disabilities often find academic work increasingly challenging in higher grades as the demands intensify and the curriculum becomes more abstract. Nonetheless, attributing all of Max's current difficulties to his ID, as the school psychologist has done, may be misguided. Unfortunately, this tendency to assume that all functional impairments in a person with a given disability may be attributed to the disability is an error that physicians and sometimes school personnel commonly make. To avoid this type of assumption, or diagnostic overshadowing, a patient's functioning should be evaluated in different domains, and the physician should avoid equating a patient's functioning in any domain with a diagnosis.

Max's declining grades, in the context of significant social stressors such as his parents' divorce and his grandfather's death, may be indicative of depression, a common comorbidity of ID. At this visit, assessing or evaluating for depression with a standardized measure and considering referral for mental health evaluation and treatment would be prudent. Although not a factor in this particular case, another common comorbidity in adolescents with cognitive impairment is anxiety, which may be interpreted as attention-deficit/hyperactivity disorder (ADHD) or as a behavior problem. Anxiety or depression may not be obvious during an office visit, particularly in the context of cognitive impairment. Depression and anxiety disorders are at least as prevalent in individuals with ID as in the general population, and some studies have shown an increased prevalence. Therefore, standardized assessment is recommended to increase detection of these common comorbid conditions.

In all adolescents, particularly those with disabilities or chronic health conditions, some thought should be given to planning for the transition to adulthood. Max will likely need considerable support in managing his diabetes care. Even if Max had no chronic health conditions, careful planning for adulthood is warranted. Between the ages of 14 and 16 years, all

students with IEPs should be invited to the IEP meetings and begin to make substantive contributions to vocational and educational planning. Max and his family should start thinking about where and with whom Max is going to live when he becomes an adult. What supports will he continue to need? What interventions are necessary now to prepare Max adequately to succeed with minimal supports?

As Max's pediatrician, some thought should be given to the transfer of Max's care to an internist. How can the primary care physician support Max in finding a physician for this young man with complex needs? Adolescents with disabilities should make regularly scheduled visits throughout adolescence to organize their transition process. The primary care physician can play a helpful role in pooling input from various pediatric subspecialists before transferring care to an internist and adult subspecialists. A primary care physician who has a long-standing relationship with an adolescent can also assist the adolescent and family by providing counseling related to sexuality issues or by referring to an appropriate resource for sexuality education for adolescents with intellectual disabilities. A subspecialist with training in developmental and behavioral pediatrics or in neurodevelopmental disabilities can facilitate and organize transition planning. The International Classification of Functioning is a useful organizing framework (Table 278-2).

### Case 3

*Hannah Ruiz is an 8-year-old new patient to your practice with a diagnosis of Coffin-Siris syndrome, a very rare congenital malformation syndrome, including prenatal-onset growth deficiency, mild to moderate ID, moderate to severe hypotonia, seizures, coarse facies, hirsutism, and hypoplastic to absent fifth distal phalanges. She is accompanied by her mother and maternal grandmother. During the interview, Mrs Ruiz tells you proudly that Hannah's IQ is 88, which the geneticist said is one of the highest IQs ever reported for anyone with Coffin-Siris syndrome. She then mentions that this*

*situation is a source of confusion for her, given that Hannah is not doing well in school despite the fact that she has normal intelligence.*

*During the interview, Hannah requires constant redirection by her mother and grandmother. She bolts out into the hallway on several occasions. When seated, she fidgets continuously. During the examination, Hannah grabs at the stethoscope and the otoscope. Her speech is difficult to understand because of severe articulation problems. Her allergies are clearly in full force, with her nose continually running. Her mother wipes her nose frequently during the visit, to which Hannah objects strenuously. Her mother asks whether you have any thoughts about her academic difficulties.*

### Case 3 Discussion

Hannah clearly does not have a cognitive disability, with an IQ in the normal range at 88. Although most people with Coffin-Siris syndrome have moderate to severe ID, she is an exception. This situation illustrates the important point that functional assessments are much more useful than diagnostic labels or genetic diagnoses in estimating abilities and in developing care plans. Although Hannah's general intelligence is technically in the normal range, it is clearly in the low-normal range, and she would be expected to be a slow learner. She may have significant discrepancies among various subscales that may be affecting her school performance, for which she would qualify for a diagnosis of learning disability. Furthermore, her adaptive skills are clearly impaired. Hannah's academic performance is being affected by inattention, hyperactivity, and impulsivity. In summary, Hannah has significant impairment of adaptive functioning but not of intellectual functioning; therefore, she does not qualify for a diagnosis of ID.

The discrepancy between Hannah's IQ and her academic achievement may be the result, in part, of inattention and hyperactivity, but the explanation is likely to be more complex given the many components of IQ. Comprehensive cognitive and academic testing

**Table 278-2**

### International Classification of Functioning, Disability, and Health to Organize Evaluation and Care Plan

DOMAINS	ELEMENTS TO INCLUDE IN EVALUATION
Learning and applying knowledge General tasks and demands Communication	Learning, thinking, problem solving, and decision making Carrying out tasks, organizing routines, handling stress Use of language, signs, and symbols; receiving and producing messages; carrying on conversation; use of communication devices and techniques
Mobility	Moving body position or location; transferring from one place to another; carrying, moving, and manipulating objects; walking running, and climbing; using transportation
Self-care Domestic life	Washing, dressing, grooming, eating, drinking, hygiene, health practices Acquiring food, clothing, and place to live; household chores; assisting others
Interpersonal interactions and relationships	Basic and complex interactions with people, including strangers, friends, relatives, immediate family members, and intimate relations in a socially appropriate manner
Major life areas Community, social, and civic life	Carrying out tasks related to education, work, and economic transactions Recreation and leisure, religion or spirituality, political life or citizenship

would help in identifying specific learning disabilities and in guiding the design of appropriate learning supports. Hannah's parents can request of her principal that school personnel perform a multidisciplinary evaluation for the identification of learning disabilities; the physician can support the family by explaining this process (see When to Refer).

Although IQs are generally considered to be stable over time for any given individual, seeing some change in IQs in children with learning disabilities is not uncommon. For example, at an early age, Hannah may have achieved an IQ in the normal range, largely owing to strong memory skills. Over time, as IQ tasks favor reasoning over rote memorization, and calculations require multiple steps, Hannah's score would then drop significantly. Notably, this situation would not represent a true regression, but would be a phenomenon of standardized testing. In addition, depending on which test instrument was used, and when it was used, an erroneously elevated IQ score may have been given; as these tests are revised and upgraded, different versions of the same test do not yield comparable results.

Considering Hannah's adaptive impairments, she would likely benefit from care coordination for services through state or local programs for ID. Having psychological assessments repeated as she progresses through school would likely be to Hannah's advantage, both to guide her IEP and to identify if she might qualify for a diagnosis of ID with its accompanying service qualifications. An important point to bear in mind, however, is that Mrs Ruiz is proud of Hannah's relatively high IQ and that such a diagnostic reclassification would need to be handled sensitively despite the advantages it would bring to Hannah.

Hannah has significant symptoms of inattention, hyperactivity, and impulsivity, which may represent ADHD. Such symptoms are common comorbidities of learning disabilities and ID. Effective interventions are available for inattention, hyperactivity, and impulsivity, including school accommodations and medications.

#### Case 4

*Gavin Park, a 2½-year-old boy, is accompanied by his parents in your office. This session is the first follow-up appointment since Gavin established care with you 3 months ago. At the initial visit, you noted significant delays in speech and motor development, and you referred the family to Early Intervention (EI) (partially federally funded, locally provided developmental services for children birth to 3 years of age). In the evaluation for EI, Gavin's developmental level was found to be at approximately 18 months in all domains. Mr and Mrs Park are very pleased with the EI services they have received. They note that Gavin is making good progress in his new preschool. Today, they want your opinion about Gavin's prognosis.*

#### Case 4 Discussion

Gavin is a toddler with moderate global developmental delays. At the chronologic age of 30 months, Gavin is functioning at a mental and motor developmental age of 18 months based on Bayley Scales of Infant

Development (III) standardized testing. This results in a developmental quotient (DQ) of approximately 60 for both mental and motor development. (The DQ equals the developmental age on standardized tests of, for example, intelligence, language, or motor, divided by the chronologic age with this fraction then multiplied by 100.) Cognitive and adaptive skills are included together in the DQ-mental. With a DQ between 2 and 3 standard deviations below the mean, Gavin is at high risk for having ID. For Gavin to catch up, not only would he have to make developmental progress at a rate commensurate with his peers, but he would also have to actually accelerate in his development such that he would outpace his peers. Gavin is making some nice progress in EI, but considering the global nature of his delays, he will not likely accelerate in his development. However, it should be noted here that in circumstances in which the cause of the delays can be identified and reversed, such as elimination of neglect or abuse, or diagnosis and treatment of a metabolic disorder, children may demonstrate such acceleration in development that they can "graduate" from severe to milder delays or from mild delays to typical development.

Nevertheless, making a diagnosis of ID is unnecessary at this point. A diagnosis of ID would likely be difficult for the family to hear and would not be necessary for Gavin's ability to obtain appropriate services. Therefore, the most appropriate diagnosis at this point would be global developmental delay. Although the diagnosis of ID may be deferred, the opportunities for appropriate and early interventions and diagnostic workup should not be delayed. Gavin is already receiving EI services. All children with global or isolated developmental delays should be referred to EI and considered for specialized medical evaluations (because EI is *not* a medical program). Early Intervention physicians should be working with the family to develop an appropriate transition plan for special education services through the school district to start after the child turns 3 years of age. Even when the physician is uncertain that a significant delay exists, if the parents are concerned about their child's development, then their concerns should be validated by encouraging this evaluation. Children with global developmental delay should also be evaluated for possible causes of their developmental differences. Physical examination findings that may suggest the cause of the delays are available in Table 278-3, Table 278-4, and Table 278-5. Table 278-6 provides recommendations regarding the diagnostic workup for children with global developmental delay.

#### EVALUATION

A diagnosis of ID requires documentation of impairment of cognition and of adaptive functioning acquired during development. A useful framework for organizing the collection of these data, and for organizing the care plan, is provided by the *International Classification of Functioning, Disability and Health* (ICF) (see Table 278-2). The ICF was developed by the World Health Organization in 2002 in response to criticism that the 10th edition of the *International Statistical Classification of Diseases and*

**Table 278-3****Minor Anomalies Seen in Specific Syndromes Associated With Intellectual Disability**

SYNDROME	SIGNIFICANT FEATURES ON PHYSICAL EXAMINATION
Down syndrome	Brachycephaly, microcephaly, epicanthal folds, Brushfield spots, up-slanting palpebral fissures, small ears, small nose with low nasal bridge, brachydactyly and clinodactyly, single transverse palmar crease, wide gap and plantar crease between first and second toes, hypotonia, short stature
Fragile X syndrome	High forehead, long jaw or face, large protuberant ears, velvety palmar skin with dorsal redundancy, hyperextensible joints, peripubertal macroorchidism, early-onset overgrowth, initial shyness, repetitive behaviors and stereotypes (note that many of these characteristic dysmorphic features may not be apparent in the younger child)
Fetal alcohol syndrome	Microcephaly, short palpebral fissures, maxillary hypoplasia, flat philtrum, thin upper lip, small distal phalanges and small fifth fingernail, joint anomalies of position and function, short stature
Williams syndrome	Stellate iris, short palpebral fissures, medial eyebrow flare, periorbital fullness, flat nasal bridge, anteverted nares, long philtrum, prominent lips, hoarse voice, heart murmur, hyperactive deep-tendon reflexes, friendly personality, hyperactivity, short stature
Velocardiofacial syndrome (VCFS)	Narrow palpebral fissures, cleft palate, velopharyngeal insufficiency, prominent nose with narrow base, abundant scalp hair, long face, retruded mandible, heart murmur, slender, hypotonic limbs with hyperextensible hands and fingers (note that VCFS is a contiguous gene syndrome and, as such, exists in a spectrum with DiGeorge syndrome)
Rett syndrome	Acquired delay in head growth, acquired diminished eye contact and loss of speech, repetitive purposeless midline hand movements such as wringing or washing, apraxia, hypotonia (principally in girls)

**Table 278-4****Nonspecific Dysmorphic Features Associated With Anomalous Brain Development**

FEATURE	ABNORMALITY	PATHOGENESIS OR POSSIBLE SIGNIFICANCE
Cranium	Microcephaly Asymmetry	Reduced brain growth Premature suture fusion vs deforming external forces vs abnormal underlying brain growth
Hair	Absent or multiple (>2) parietal whorls Cowlick, or anterior upsweep of scalp hair	Abnormal brain development between 10 and 16 weeks' gestation Posterior displacement of junction of parietal and frontal hair streams, resulting from reduced frontal brain development
Eyes	Short palpebral fissures Up-slanted palpebral fissures	Deficient frontal brain growth Relatively deficient frontal brain growth compared with midface
Ears	Low-set (top of helix below outer canthi) Posterior rotation (axis tilted backward >15 degrees)	Reflects delayed morphogenesis because ears are low-set in the early fetus Reflects delayed morphogenesis because ears are posteriorly rotated in the early fetus
Mouth	High arched	Persistent lateral palatal ridges, indicative of oral hypotonia or other oral-motor dysfunction

*Related Health Problems* emphasized diagnostic labels over function and consequently maintained the equation of disability with poor health. With an emphasis on function over diagnostic labels and consideration of environmental factors, the ICF provides a framework for assessment that is congruent with the guidelines put forth by the AAIDD, which were enumerated earlier. Practically speaking, for the primary care physician, the ICF can serve as a *review of functional status*, which complements the review of systems of the traditional medical model. The primary care physician may use Table 278-2 to

assist with the thorough review and documentation of functioning of a comprehensive set of domains during the medical interview and during formation of the care plan.

## PHYSICAL EXAMINATION AND LABORATORY TESTS

The physical examination does more than point to a possible diagnosis. In addition to determining potential causes of ID, the physical examination plays an important role in establishing a connection with the

**Table 278-5** Neurocutaneous Findings Associated With Intellectual Disability

SYNDROME	FINDINGS ON PHYSICAL EXAMINATION	DESCRIPTION
Tuberous sclerosis complex	Hypomelanotic macules	Oval or ash-leaf shaped, few mm to cm, mostly on trunk or extremities; may occur in infancy
	Shagreen patches	Firm yellow to red clusters of nodules, few mm to cm, on dorsum of body, particularly lumbosacral area; typically occurring at puberty (less commonly before)
	Facial angiofibroma	Pink or red shiny nodules on face, especially on nasolabial folds; usually appearing between 2 and 5 years of age
	Forehead fibrous plaque	Yellow-brown or flesh-colored, raised soft or hard plaque, few mm to cm, on forehead or scalp; can occur at any age
	Periungual fibroma	Reddish or flesh colored, arising from nail bed or cuticle, found on toes more often than fingers; usually occurring at puberty or later
Neurofibromatosis	Café au lait macules	Usually hyperpigmented but also includes hypopigmented macules 5 mm or greater
	Axillary freckling	Small brown macules in axillae and perineum
	Cutaneous neurofibroma	Small, raised, soft, pigmented nodules
Sturge-Weber syndrome	Cranial port-wine stain	Light pink to deep purple birthmark, typically involving at least 1 upper eyelid and the forehead

**Table 278-6** Diagnostic Workup for Global Developmental Delay or Intellectual Disability<sup>a</sup>

TEST	INDICATIONS
Ophthalmologic assessment	Recommended in all children with moderate to severe global developmental delay or ID.
Audiologic assessment	Recommended in all children with moderate to severe global developmental delay or ID.
Karyotype	Recommended in all children with moderate to severe global developmental delay or ID.
Metabolic workup	Not generally recommended if newborn screen is documented; recommended with specific family history, consanguinity, regression, or episodic decompensation
Fragile X syndrome (DNA methylation testing)	Recommended in boys with moderate to severe global developmental delay or intellectual disability (ID); particularly recommended when characteristic features present (see Table 278-4).
Rett syndrome ( <i>MECP2</i> gene testing)	Recommended in girls with moderate to severe global developmental delay or ID; particularly recommended when characteristic features present (see Table 278-4).
Subtelomeric fluorescence in situ hybridization (FISH) <sup>b</sup>	Before the development of complete genomic hybridization technology, this was the best test for the detection of small subtelomeric rearrangements. This test has been replaced by microarray comparative genomic hybridization.
Microarray comparative genomic hybridization <sup>c</sup>	Consider in mild to severe global developmental delay or ID. This test has higher yield when 1 or more of the following features are present: family history of unexplained moderate to severe ID, prenatal onset growth restriction, or postnatal growth abnormalities, including microcephaly or macrocephaly or short or tall stature, more than 2 dysmorphic facial features or nonfacial congenital anomalies.
Thyroid function testing	Recommended if no newborn screen documented or with characteristic symptoms, such as late tooth eruption or fontanel closure, weight for age above height for age, constipation, delayed relaxation phase of deep-tendon reflexes.
Lead testing	Has been found to be elevated at higher rate in children with risk factors and global developmental delay or ID compared with children with risk factors without, given that pica is a behavioral characteristic associated with ID.
Electroencephalogram	Recommended only if a clinical indication of seizures is present.
Brain magnetic resonance imaging	Recommended for global developmental delay, although clinical picture should be taken into account. Lower yield in mild global developmental delay, which tends to be familial. Higher yield with focal or abnormal neurologic examination, in the presence of cranial anomalies (see Table 278-4) or neurocutaneous features (see Table 278-5).

<sup>a</sup>Many of these tests are generally ordered by subspecialists. This information is provided to give the generalist an idea of the workup for ID.<sup>b</sup>DNA complete genomic hybridization microarray technology has replaced subtelomeric FISH.<sup>c</sup>Consensus Statement: Chromosomal microarray is a first-tier clinical diagnostic test for individuals with developmental disability or congenital anomalies. *Am J Hum Genet.* 2010;86(5):749–764.

child and in assessing interpersonal interactions. Table 278-3 summarizes key features of some common syndromes associated with ID. Table 278-4 summarizes findings that, although not pathognomonic of particular syndromes, may indicate anomalous brain development. Table 278-5 summarizes and describes the features of selected neurocutaneous syndromes.

In most cases of mild ID, the cause is multifactorial; no single cause is identified or, indeed, identifiable. In contrast, in cases of moderate to severe ID, a single cause is more commonly implicated and may be identified by systematic investigation, including through physical examination. An aspect of the examination that deserves special mention is the formal assessment of hearing and vision; referrals for thorough evaluation of these senses should be made in the workup of global developmental delay or ID. In the absence of clues from the physical examination, guidelines from the American Academy of Neurology may be used for the diagnostic workup of ID and global developmental delay. These guidelines are summarized in Table 278-6.

### WHEN TO REFER

- Infants and toddlers failing to meet developmental milestones using standard screening and surveillance instruments, such as Ages & Stages Questionnaires, the Child Development Inventory, or Bright Futures Guidelines, should be referred to Early Intervention (EI) for evaluation. In addition, if a parent expresses concern, a pediatrician may refer for evaluation through the EI program even if in-office screens do not detect developmental delays. Referrals can be based on objective criteria or clinical judgment. If the primary care physician even suspects developmental delay, erring on the side of caution would be advisable.
- Parents who express concerns about their child's development should have their concerns validated by a referral to EI services.
- Children who have had a new diagnosis of global developmental delay or of ID should have a complete medical evaluation to determine the causes of the delays. The primary care physician may wish to refer to subspecialists in genetics, neurology, developmental and behavioral pediatrics, or neurodevelopmental disabilities to assist with this evaluation.
- Children who are suspected of having ID and who have not had a formal psychological assessment should be referred for evaluation of cognitive abilities, academic achievement, and adaptive skills. Families may obtain such psychological testing free of charge through their local school district by making a formal request for a multidisciplinary evaluation. Primary care physicians can support families in this endeavor by providing references to the process of requesting an evaluation through the school district. Families may also obtain an independent psychological evaluation from a private pediatric psychologist or pediatric neuropsychologist.

### ACKNOWLEDGMENT

*I dedicate this revision to my original coauthor and mentor, Bill Cohen. Also, I would like to thank Dr Anne Tsai for helpful comments on this revision.*

## Chapter 279

# IRON-DEFICIENCY ANEMIA

Lakshmanan Krishnamurti, MD

Iron-deficiency anemia (IDA) is the most common nutritional deficiency worldwide. In the United States, it is most common among women and young children. It affects 2.4 million US children. Iron is an important ingredient of hemoglobin and is involved in numerous cellular processes. Children with iron deficiency in infancy continue to have poorer cognition and school achievement and more behavior problems into middle childhood. Iron deficiency is also associated with deficits in work productivity, and severe anemia is associated with maternal and child mortality. Prevention of iron deficiency in early childhood is, therefore, an important public health issue.

## IRON-CONTAINING COMPOUNDS IN THE BODY

Iron is the most abundant heavy metal in the body. The multiple iron-containing compounds serving metabolic functions include heme- and nonheme-containing compounds. Heme is composed of a protoporphyrin ring with noncovalently bound iron in the ferrous form ( $\text{Fe}^{2+}$ ). The most abundant heme-containing protein in the body is hemoglobin, which transports oxygen from the lungs to the tissues and accounts for more than 60% of total body iron. Myoglobin, which accounts for 10% of total body iron, is a heme protein that provides oxygen for use during muscle contraction. The other major heme proteins, the cytochromes, are found in the mitochondria and are necessary for the oxidative production of cellular energy. There also are several nonheme iron proteins, such as the iron-sulfur complexes and flavoproteins. Many of these proteins are found in the mitochondria and also are involved in oxidative metabolism.

## REGULATION OF IRON ABSORPTION, HOMEOSTASIS, AND STORAGE

Basic studies in humans and in a variety of animal models have helped define the pathways and transporters involved in iron absorption and the signal transduction mechanisms involved in iron homeostasis. Divalent metal transporter-1 (DMT-1) mediates absorption of iron in duodenal and jejunal enterocytes and in the delivery of iron to erythroid precursors. Body iron stores, ineffective erythropoiesis, and

hypoxia, as well as dietary factors such as phytate, polyphenols, calcium, and ascorbic acid, regulate iron absorption. Ferroportin is a transmembrane protein found in all cells involved in iron transport that mediates iron export from enterocytes and from macrophages recycling senescent red blood cells (RBCs) to plasma. Hepcidin is a negative regulator of iron export that inhibits export of iron to plasma by binding to ferroportin and removing it from the cell surface. Anemia, defective erythropoiesis, iron stores, hypoxia, and inflammation regulate hepcidin. Hemojuvelin (HJV) is a membrane-bound and soluble protein that regulates hepcidin expression. Membrane-bound HJV is a critical part of the signaling mechanism for hepcidin transcription. The soluble form of HJV functions as a competitive inhibitor of the membrane-bound HJV. High levels of transferrin-bound iron in the plasma inhibit the production of soluble HJV, leading to hepcidin-mediated inhibition of iron transport into the plasma by ferroportin. Ceruloplasmin and hephaestin are enzymes that oxidize ferrous iron exported by ferroportin to ferric form to facilitate plasma transport of iron by transferrin. Transferrin is a  $\beta_1$ -globulin capable of binding atoms of iron in the ferric form. It transports iron from the intestinal epithelium to the bone marrow, where it binds to transferrin receptors on the surface of differentiating RBCs. The transferrin receptor complex is then internalized and thus supplies iron for the synthesis of hemoglobin. Transferrin also mediates transport of iron exported out of macrophages recycling senescent RBCs. Ferritin, an iron storage compound found in all cells of the body, is composed of a hollow protein shell encapsulating iron molecules. Hemosiderin, which also serves to store intracellular iron, is thought to be a partially degraded form of ferritin.

## PREVALENCE OF IRON DEFICIENCY AND IRON-DEFICIENCY ANEMIA

Iron deficiency is common, despite the generally good standard of nutrition and the widespread use of iron-fortified foods. The prevalence of iron deficiency is greatest among toddlers aged 1 to 2 years and adolescent girls and adult women aged 12 to 49 years. The prevalence of iron deficiency is 2 times higher among non-Hispanic black and Mexican American women (19% to 22%) than among non-Hispanic white women (10%). The National Health and Nutritional Examination Survey (NHANES) revealed that prevalence of iron deficiency between 1988–1994 and 1999–2002 remained unchanged at 9% in children 1 to 2 years of age. The prevalence of iron deficiency increased from 4% in 1988–1994 to 6% in 2003–2006 in children 3 to 4 years of age. Thus, the prevalence of IDA remains higher than the goal of the national health objectives for 2010, and no significant progress was made toward the goal to reduce iron deficiency in vulnerable populations by 3 to 4 percentage points.

## ETIOLOGY AND PATHOPHYSIOLOGY

The 4 most important factors in the development of iron deficiency in children are the iron endowment at birth, the iron needs during rapid body growth,

**Table 279-1** Causes of Iron Deficiency

**INCREASED IRON REQUIREMENTS**

- Blood loss
  - Menstruation
  - Gastrointestinal tract
    - Milk enteropathy
    - Food sensitivity
    - Inflammatory bowel disease
    - Meckel diverticulum
    - Peptic ulcer disease
    - Reflux esophagitis
    - Hookworms
    - Malignancy
- Genitourinary tract
- Respiratory tract
  - Idiopathic pulmonary hemosiderosis
  - Cystic fibrosis
  - Pulmonary tuberculosis
- Cardiac
  - Hemosiderinuria caused by cardiac hemolysis
- Blood donation
- Pregnancy
- Growth
  - Prematurity
  - Infancy
  - Adolescence

**INADEQUATE IRON ABSORPTION**

- Diet low in bioavailable iron
  - Formula not fortified with iron
  - Cow milk before the age of 6 months
  - Strict vegetarian diet
  - Poor dietary habits in adolescents
- Impaired absorption
  - Intestinal malabsorption
  - Gastric surgery
  - Hypochlorhydria

Modified from Centers for Disease Control and Prevention. Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep.* 1998;47(RR-3):1–29.

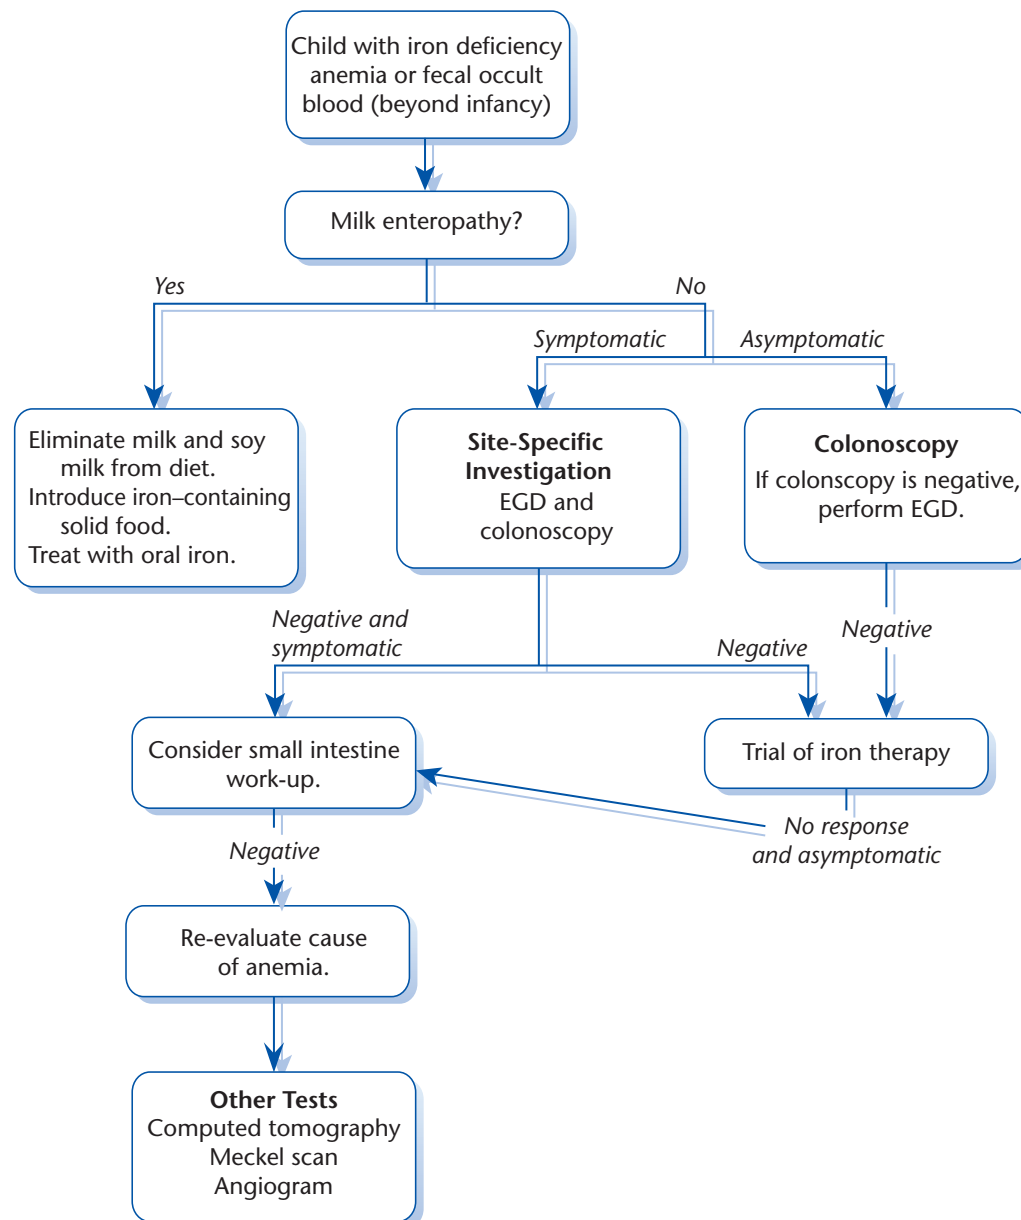

exogenous iron absorption, and blood loss. The causes of iron deficiency are summarized in Table 279-1.

During gestation, the level of iron stores in newborns is related to maternal iron status, and the maternal-fetal unit is dependent on exogenous iron. The ratio of iron content to weight in the human fetus remains constant throughout gestation. The healthy full-term infant has sufficient iron stores to last for 6 months, if sufficient small amounts of iron are ingested from the diet. The infant's iron endowment can be compromised by blood loss during the pregnancy or the perinatal period. Common causes of blood loss include third-trimester bleeding, such as abruptio placentae, placenta previa, fetomaternal hemorrhage, and twin-to-twin transfusions.

Gestational conditions that result in lower newborn iron stores include severe maternal iron deficiency, maternal hypertension with intrauterine growth restriction, and maternal diabetes mellitus. Stable, very low-birth-weight (VLBW) premature infants are also at risk for early postnatal iron deficiency because they accrete less iron during gestation, grow more rapidly after birth, are typically undertreated with enteral iron, and receive fewer RBC transfusions than sick VLBW infants. Iron is needed not only for many metabolic functions and tissue replacement, but also for growth. Growth rates vary with age and are maximal during infancy and adolescence, the same

periods associated with the highest frequency of iron deficiency.

Iron balance is maintained by regulation of iron absorption. The amount of iron absorbed depends on the amount and the bioavailability of dietary iron, as well as on regulation of iron absorption by the intestinal mucosa. Most dietary iron occurs in the nonheme form and is much less bioavailable than that in heme proteins. The iron in hemoglobin and myoglobin is particularly bioavailable; up to 30% is directly absorbed by the gastrointestinal tract. Human milk and cow milk contain small amounts of iron (0.2 to 0.3 mg/1,000 mL). However, 50% of the iron in breast milk is absorbed, compared with only 10% in cow milk. Full-term infants who are exclusively breastfed for the first 6 to 9 months do not become iron deficient. In a double-blind randomized study, Friel and colleagues demonstrated that iron supplementation starting at 4 months of age resulted in higher hemoglobin and mean corpuscular volume at 6 months of age and significantly higher visual acuity and psychomotor developmental index at 13 months. Exclusive breastfeeding beyond 6 months of age is associated with an increased risk for iron deficiency by 9 months. Iron deficiency at 6 months is related to growth velocity. Bran in cereals, polyphenols in many vegetables, and tannins in tea inhibit nonheme iron absorption. Complementary foods, including iron-fortified cereals,

**Figure 279-1** Algorithm for approach to iron deficiency with occult intestinal blood loss. EGD, esophagogastroduodenoscopy. (Modified from Feldman M. Sleisenger & Fordtran's Gastrointestinal and Liver Disease. 7th ed. Copyright © 2002 Elsevier, with permission.)

vegetables with high iron content, and red meats, should be introduced early.

Blood loss causes iron deficiency in children less frequently than in adults. In infancy and childhood, iron deficiency caused by blood loss is most commonly associated with the ingestion of unprocessed cow milk and with parasitic infections. Hypersensitivity to whole cow milk causes an exudative enteropathy and frequently leads to gastrointestinal blood loss (Figure 279-1). Other less common causes of blood loss in children include Meckel diverticulum, intestinal duplication, peptic ulcer disease, hemorrhagic telangi-

ectasia, and the chronic use of medications that prolong the bleeding time (eg, nonsteroidal anti-inflammatory drugs).

### STAGES OF IRON DEFICIENCY

Iron deficiency occurs when total body iron content is diminished. When absorption exceeds losses, the iron surplus is stored in the reticuloendothelial system, principally the liver, spleen, and bone marrow. Iron is removed from the reticuloendothelial storage pool to compensate for negative iron balance. The development of iron deficiency proceeds through a series of

overlapping stages. The major public health importance of iron deficiency is that it is associated with significant neurodevelopmental and long-lasting behavioral problems. Therefore, it is important to identify, prevent, and manage iron deficiency before the development of hematologic complications with IDA.

Iron deficiency is considered to develop in 3 stages. The first stage of iron deficiency is storage iron depletion. During this stage, there is no deficit of iron supplied to the erythroid marrow for RBC production. The decrease in body iron stores is typically measured by serum ferritin. If the negative iron balance continues, the second stage, iron-deficient erythropoiesis (IDE), will occur. During this stage, erythroid iron supply is diminished, but the hemoglobin concentration remains in the normal range. Serum transferrin saturation is increased in the first or second stage of iron deficiency. In this stage, soluble transferrin receptors (sTfRs) are increased, zinc protoporphyrin (ZnPP), is increased, and reticulocyte hemoglobin concentration (CHr) is decreased. If the negative iron balance persists, IDA finally develops. This third stage is characterized by a decrease in the hemoglobin concentration and a reduction in RBC size and hemoglobin content. Hematologic abnormalities in iron deficiency progress as there is progressive impairment of hematopoiesis. Anisocytosis and an increased percentage of microcytic cells are the first hematologic abnormalities; at the second stage the mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) decline; and the final stage of iron deficiency is associated with a low MCHC and low hemoglobin concentration.

Functional iron deficiency is a condition that occurs primarily as a result of treatment with recombinant human erythropoietin. During the supraphysiologic burst of RBC production after a pharmacologic dose of recombinant human erythropoietin, the small circulating iron pool (0.1% of total body iron) may be insufficient to supply the stimulated erythron. Thus, even with normal iron stores, IDE may occur, with further iron repletion often required for normal erythropoiesis to resume. Inflammation may also be a contributory factor.

Specific laboratory findings are associated with each of the 3 stages of iron deficiency. The laboratory test findings characteristic of each stage are summarized in Table 279-2.

## DIFFERENTIAL DIAGNOSIS

Diagnosis of iron deficiency is made by the combination of RBC indices and serum transferrin saturation or ferritin. Transferrin saturation and ferritin may be altered by infection, inflammation, malignancy, and starvation. Serum transferrin receptor levels help discriminate iron deficiency from the anemia of inflammation or chronic disease.

Although the absence of iron stores in the bone marrow remains the gold standard for making the diagnosis of iron deficiency, this test is rarely performed for this purpose because of the obvious discomfort involved and the difficulty of standardizing bone marrow iron stain.

After the diagnosis of IDA is made, efforts should be undertaken to establish the cause of the deficiency

**Table 279-2**

### Laboratory Abnormalities in the 3 Stages of Iron Deficiency

STAGE	DESCRIPTION
I: Iron depletion	Serum ferritin ↓ Bone marrow iron ↓
II: Iron-deficient erythropoiesis	Serum ferritin ↓ Bone marrow iron ↓ Serum iron ↓ TIBC ↑
III: Iron-deficiency anemia	Serum iron ↓ Serum ferritin ↓ Bone marrow iron ↓ TIBC ↑ Hemoglobin ↓ Hematocrit ↓ MCV ↓ RDW ↑

↑ Indicates increased; ↓, decreased.

MCV, mean corpuscular volume; RDW, red blood cell distribution width;

TIBC, total iron-binding capacity.

From Roper D, Stein S, Payne M, Coleman M. Anemias caused by impaired production of erythrocytes. In Rodak BF, ed. *Diagnostic Hematology*. Philadelphia, PA: WB Saunders; 1995. Reprinted by permission.

(Table 279-1). In infancy (a period when iron demands resulting from rapid growth may outstrip the supply of iron), in adolescence, and during pregnancy, iron deficiency and IDA are the result of a physiologic increase in iron requirement that is not being met by the oral supply of iron. Beyond infancy, blood loss is the most common cause of iron deficiency and IDA.

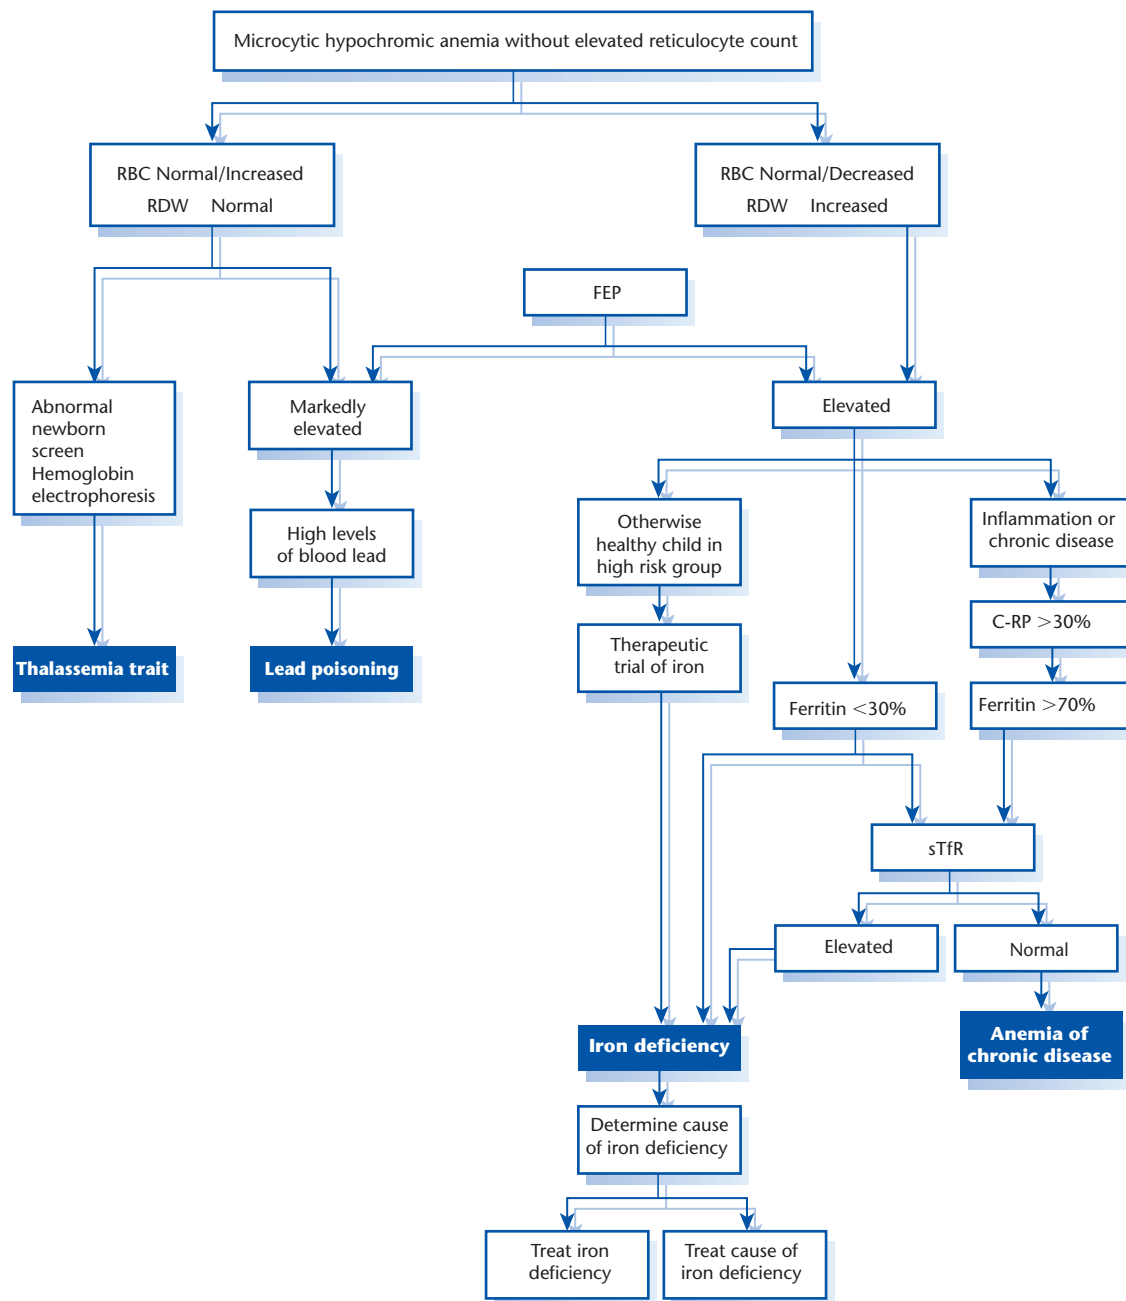

Iron-deficiency anemia must be distinguished from other causes of hypochromic microcytic anemia (Figure 279-2). Red blood cell indices in infancy and childhood are described in Table 279-3.

## Thalassemia Trait

Iron-deficiency anemia and thalassemia trait are the most common causes of mild microcytic anemia with hemoglobin 9 g/dL or more. Red blood cell count often is increased above normal despite the presence of a mild anemia and microcytosis in thalassemia trait, whereas RBC count is reduced in IDA. The RBC distribution width (RDW) is increased in iron deficiency. The Mentzer index, defined as the MCV divided by the RBC count in millions, can help distinguish the anemia of iron deficiency from that of  $\beta$  thalassemia trait. In IDA, the Mentzer index often is greater than 13.5; in  $\beta$ -thalassemia trait, it is less than 11.5 with 82% specificity. An RDW index (RDWI), which is calculated by the formula  $RDWI = (MCV/RBC \times RDW)$ , of at least 220 is indicative of IDA, whereas an index of less than 220 is indicative of thalassemia trait with a specificity of 92%. RBC count and RDWI are the most reliable discrimination indices in differentiation between  $\beta$ -thalassemia trait and IDA.

If  $\alpha$ - and  $\beta$ -thalassemia trait or hemoglobin E disease is suspected, the diagnosis can be established

**Figure 279-2** Algorithm for an approach to microcytic anemia. *C-RP*, C-reactive protein; *FEP*, free erythrocyte protoporphyrin; *RBC*, red blood cell; *RDW*, red blood cell distribution width; *sTfR*, soluble transferrin receptor.

by reviewing the newborn screen or by obtaining a hemoglobin electrophoresis. Electrophoretic methods can be diagnostic in the case of  $\beta$ -thalassemia or hemoglobin E, but may not be informative in  $\alpha$ -thalassemia beyond the newborn period. Because  $\beta$ -thalassemia or hemoglobin E trait or homozygous hemoglobin E is frequently not associated with hemoglobin of less than 9 g/dL, it is not included in the differential diagnosis in severe anemia. However, patients who are double heterozygotes for  $\beta$ -thalassemia and hemoglobin E may have moderate to severe

anemia. Diagnosis of  $\alpha$ -thalassemia trait can be assumed when a child with a familial hypochromic microcytic anemia has normal results of iron studies (including ferritin), normal levels of hemoglobin A<sub>2</sub> and hemoglobin F, and a normal hemoglobin electrophoresis. It is a diagnosis of exclusion, except in the newborn period, when infants with  $\alpha$ -thalassemia trait have 3% to 10% hemoglobin Barts ( $\gamma_4$ ), which may be detected in the newborn screen if there is a mutation involving the deletion or loss of function of 1 or more of the  $\alpha$ -globin genes.

**Table 279-3** Red Blood Cell Indices During Infancy and Childhood

AGE	HEMOGLOBIN (G/DL)		HEMATOCRIT (%)		RETICULOCYTES (%)	MCV (FL)
	MEAN	RANGE	MEAN	RANGE	MEAN	LOWEST
<b>CHILD</b>						
Cord blood	16.8	13.7–20.1	55	45–65	5.0	110
2 wk	16.5	13.0–20.0	50	42–66	1.0	107
3 mo	12.0	9.5–14.5	36	31–41	1.0	80
6 mo–6 yr	12.0	10.5–14.0	37	33–42	1.0	70–74

### Hemoglobin H Disease

Hemoglobin H disease, another form of  $\alpha$ -thalassemia, results from deletion of 3 of the 4  $\alpha$ -globin genes. It also is characterized by hypochromia and microcytosis, but, in addition, there is a mild hemolytic component from instability of the  $\beta$ -chain tetramers (Hb H) resulting from a deficiency of  $\alpha$ -globin chains. Beyond infancy, Hb H is readily identified by hemoglobin electrophoresis. During the newborn period, the moderately severe  $\alpha$ -globin deficiency allows for the accumulation of more  $\gamma$  chains, and the concentration of hemoglobin Barts is more than 20%.

### Anemia of Chronic Disease and Inflammation

Inflammation impairs the supply of iron to the plasma and ultimately results in a form of anemia called *anemia of chronic disease* or *anemia of inflammation*. It is usually normocytic, although, occasionally, it may be slightly microcytic. Because inflammation alters screening tests for iron status in the same manner as true iron deficiency, the distinction between anemia of chronic disease and IDA requires tissue-related iron measurements. However, the usefulness of the serum ferritin in the diagnosis of IDA is compromised by the effect of inflammation on the value. Consequently, a serum ferritin concentration below 30 mcg/L suggests IDA in the presence of inflammation. However, because specificity for iron deficiency falls sharply with increasing ferritin levels, there is considerable overlap between iron-deficient and iron-replete children, and ferritin levels between 20 and 100 mcg/L are often inconclusive, whereas serum ferritin levels higher than 100 mcg/L usually exclude iron deficiency.

C-reactive protein is generally considered to be the best laboratory marker of inflammation. If it is less than 30 mg/L, it is generally considered unlikely that the inflammation is sufficient to raise the serum ferritin. The sTfR measurement for identifying IDA is one in which the concentration is not affected by inflammation. Use of the sTfR/log ferritin ratio of more than 1.70 further improves the specificity of the diagnosis

of IDA and may eliminate the need for bone marrow examination for assessment of iron stores.

### Lead Poisoning and Anemia

Lead poisoning and IDA both are associated with high levels of erythrocyte ZnPP. Iron deficiency and lead poisoning frequently coexist. Although the nature of their relationship is not completely elucidated, characterization of a common iron-lead transporter and epidemiologic studies among children strongly suggest that iron deficiency may increase susceptibility to lead poisoning. In cases of lead poisoning associated with iron deficiency, the RBCs are morphologically similar, but coarse basophilic stippling of the RBCs is frequently prominent. Increases in blood lead, zinc protoporphyrin ratio (ZnPP/H), and urinary coproporphyrin levels are seen.

## EVALUATION

### History

The onset and progression of iron deficiency is usually gradual, and most children will not have major symptoms. Iron deficiency in infants and children is associated with generalized weakness, irritability, easy fatigability, headaches, poor feeding, anorexia, pica, and poor weight gain.

### Physical Examination

The physical examination is usually unremarkable except for marked pallor of the mucous membranes and skin. Other physical findings associated with IDA, but rarely observed, include mild hepatosplenomegaly, lymphadenopathy, glossitis, stomatitis, blue sclerae, and koilonychia (spoon-shaped nails). The physical examination is usually unremarkable except for marked pallor of the mucous membranes and skin. Most mild cases of IDA do not include pallor.

### Laboratory Evaluation

Laboratory tests for identifying iron deficiency include screening and definitive tests. Screening tests

**Table 279-4****Laboratory Findings Associated With the Differential Diagnosis of Microcytic Anemias**

FINDING	IRON DEFICIENCY	LEAD POISONING	β-THALASSEMIA TRAIT	CHRONIC DISEASE
Ferritin	↓	Normal	Normal	↑
Serum iron	↓	Normal	Normal	↑
Total iron-binding capacity	↑	Normal	Normal	↓
Erythrocyte zinc protoporphyrin	↑	↑↑	Normal	↑
Red blood cell distribution width	↑	Normal	Normal	Normal
Serum transferrin receptor	↑	Normal	↑	Normal

↑, Increased; ↑↑, very increased; ↓, decreased. Iron deficiency and lead poisoning frequently co-exist.

identify IDE by demonstrating either a reduced supply of plasma iron or poor hemoglobinization of circulating RBCs. Definitive tests identify IDA by measuring iron-related proteins derived from either the iron storage compartment in macrophages or the iron utilization compartment in RBC precursors.

### Screening Measurements

#### Hemoglobin Concentration

Although hemoglobin concentration is the most commonly used screening test for IDA, it is relatively insensitive for the diagnosis of iron deficiency because an individual with normal body iron stores must lose a large portion of body iron before the hemoglobin falls below the laboratory definitions of anemia. Further, low hemoglobin does not distinguish among the causes of anemia other than iron deficiency, and additional testing is required.

#### Serum Iron and Transferrin Saturation

Serum iron levels normally fluctuate daily, with maximal levels occurring in the morning and minimal levels in the evening. The total iron-binding capacity (TIBC) varies less than serum iron, but is harder to measure accurately. The normal TIBC is 250 to 400 mg/dL, but, as serum iron levels decrease, the TIBC increases to 450 mg/dL or more. Iron and TIBC measurements are useful in distinguishing IDA from anemia of chronic disease. Serum iron levels decrease with both, but the TIBC levels also decrease in chronic disease states (Table 279-4). The degree of iron saturation of plasma transferrin is calculated as follows: transferrin saturation = (serum iron concentration/total iron-binding capacity) × 100.

Serum iron and TIBC levels help confirm the diagnosis of iron deficiency, with a low serum iron level and a high transferrin level resulting in a transferrin saturation of less than 10% to 15%. Transferrin levels are increased in iron-deficiency states because of increased hepatic synthesis of the protein and greater liberation of apotransferrin (the transport protein without iron) from hemoglobin-synthesizing

sites. This relatively inexpensive measurement is widely available. However, marked diurnal variation in plasma iron values and the numerous clinical disorders that affect the transferrin saturation limit its use in the clinical setting. A normal or high transferrin saturation is as useful for excluding IDA as a low value is for identifying it. Among other conditions, pregnancy and oral contraceptives may be associated with elevated transferrin level and transferrin saturation, thus complicating the diagnosis of IDA. In these situations, combining laboratory studies, such as serum ferritin and sTfR, may be useful in the diagnosis of iron deficiency.

#### Red Blood Cell Indices

The development of electronic counters has made the use of RBC indices widely available for the initial screening of infants and children for iron deficiency. These tests are highly reproducible and less subject to sampling error compared with hemoglobin determinations because tissue fluid dilution does not affect RBC size. The RBCs become smaller than normal with decreased MCV, and their hemoglobin content decreases with decreased MCHC. The RDW approximates the standard deviation of the RBC population. Normal RDWs occur in the range of 12% to 17%. In IDA, there is a marked dispersion in cell volumes (sizes) so that the RDW increases. RBC indices in infancy and childhood are described in Table 279-3.

#### Zinc Protoporphyrin

A simple and reliable measurement of IDE is the erythrocyte zinc protoporphyrin level, a product of abnormal heme synthesis. Normally, a trace of zinc rather than iron is incorporated into protoporphyrin during the final step of heme biosynthesis. In states of IDE, ZnPP formation is enhanced. Increase in the ZnPP/H of greater than 80 mmol/mol is demonstrated to be a sensitive, specific, and cost-effective test for identifying preanemic iron deficiency. A major advantage of this well-established assay is the ability to

measure the ZnPP/H directly on a drop of blood on a dedicated portable instrument called a hematofluorometer. Initially, ZnPP was erroneously characterized as metal-free protoporphyrin, free erythrocyte protoporphyrin (FEP), or erythrocyte protoporphyrin. In fact, most presumed metal-free protoporphyrin in erythrocytes is now known to be largely an artifact of the analytical procedures used at the time and still used in some laboratories, which required an acid extraction that removed zinc to form metal-free or free protoporphyrin. Because about 95% of the non-heme protoporphyrin in erythrocytes is ZnPP, this procedure does not create a diagnostic problem because, in most cases, ZnPP/H is an indicator of iron available to the developing erythrocytes in the bone marrow regardless of the etiology, such as iron deficiency, inflammation, or functional iron deficiency as in chronic renal failure. Another significant limitation of the ZnPP is that with lead toxicity and even the normal range with environmental lead exposure, infections, inflammatory diseases, and protoporphyria. However, ZnPP/H is not increased in thalassemia trait. This makes ZnPP/H determinations helpful in distinguishing iron deficiency from  $\alpha$  or  $\beta$  thalassemia trait in addition to its role in screening for iron deficiency (see Table 279-4).

### Reticulocyte Hemoglobin

The mean CHR is analogous to the RBC MCHC, but with the advantage of monitoring the hemoglobinization of the most recently produced RBCs. A CHR of less than 26 pg is an early indicator of iron-restricted hematopoiesis and IDA in children. Median reticulocyte hemoglobin was 2.0 fmol in the non-iron-deficient patient group and 1.5 fmol in the iron-deficient patient group ( $P < .01$ ), with overlap between 1.2 and 2.2 fmol, which includes 90% of the data. The sTfR median was 6.4 mg/L in the iron-deficient group and 3.3 mg/L in the non-iron-deficient group ( $P < .01$ ), with 27% of the data falling into the overlapping interval of 4.6 to 14.5 mg/L. The diagnostic power of CHR is limited in patients with high MCV or with RBC disorders such as thalassemia.

### Peripheral Blood Smear

Examination of the blood smear in IDA reveals hypochromic microcytes, poikilocytes, elliptocytes, and target cells (Figure 279-3). The presence of basophilic stippling suggests associated lead poisoning. However, the RBC changes seen on the blood smear are not specific for iron deficiency. The white blood cell count and morphology in IDA are usually normal. Both thrombocytosis and thrombocytopenia occur with iron deficiency.

### Definitive Tests

The absence of stainable iron in the bone marrow is a definitive test for IDA, but is not routinely applicable for obvious reasons, and the bone marrow iron stain must be performed in standard conditions to be reliable. The 2 key definitive measurements for diagnosing iron deficiency are the serum ferritin, which measures the size of iron stores, and the serum transferrin receptor, which measures the extent of tissue iron deficiency.

**Figure 279-3** Iron-deficiency anemia. Many red blood cells are microcytic (smaller than the nucleus of the normal lymphocyte near the center of the field) and hypochromic (with central areas of pallor that exceed one-half of the diameter of the cells). (From Goldman L. Cecil Textbook of Medicine. 22nd ed. Copyright © 2004 Elsevier, with permission.)

### Serum Ferritin

Definitive serum ferritin levels vary with age during infancy and childhood. In healthy individuals, serum ferritin levels reflect body iron stores. Ferritin is an acute-phase reactant. Serum ferritin levels are increased during infections and inflammatory processes as well as with liver disease. Although low serum ferritin is diagnostic of iron deficiency, a high ferritin level associated with inflammation or liver disease does not rule out concomitant iron deficiency. In children younger than 5 years, serum ferritin levels below 12 mcg/L and less than 30 mcg/L in the presence of infection indicate iron deficiency. In children older than 5 years, serum ferritin levels higher than 15 mcg/L indicates iron deficiency.

### Serum Transferrin Receptor

The proteolytic cleavage of transferrin receptors can be measured in the serum as sTfR, which directly correlates with the total mass of erythroid precursor. The sTfR is high in iron deficiency and in conditions resulting in increased production of RBCs, including thalassemia and sickle cell disease. It is not affected by inflammation, and hence it is useful in distinguishing iron deficiency from chronic inflammatory states that do not have high sTfR (Table 279-4). Infants have higher baseline sTfR levels than do children and adults, indicating the need to establish age-specific reference values. Using NHANES data, Mei and colleagues derived the cutoff values (97.5th percentile in a defined healthy reference population) for defining elevated sTfR in the US as 6.00 mg/l for children 1 to 5 years of age and 5.33 mg/l for non-pregnant women 15 to 49 years of age. The ratio of sTfR to serum ferritin (R/F ratio) has been shown to have excellent performance in estimating body iron stores, but is limited by the lack of standardization for sTfR assays. Use of the sTfR/log ferritin ratio of more than 1.70 improves the specificity of the diagnosis of IDA.

**Table 279-5** Responses to Iron Therapy in Iron-Deficiency Anemia

TIME AFTER IRON ADMINISTRATION	RESPONSE
12–24 hr	Replacement of intracellular iron enzymes; subjective improvement; decreased irritability; increased appetite
36–48 hr	Initial bone marrow response; erythroid hyperplasia
48–72 hr	Reticulocytosis, peaking at 5–7 days
4–30 day	Increase in hemoglobin level
1–3 mo	Repletion of stores

### Bone Marrow Iron

The staining of a normal bone marrow aspirate sample with Prussian blue dye reveals the presence of iron in RBC precursors (normoblasts) and serves as a reliable index of body iron stores. In iron deficiency, the number of iron granules in normoblasts is decreased, and stainable iron in the marrow aspirate is almost completely absent. Bone marrow aspiration is almost never needed to establish a diagnosis of iron deficiency.

### Diagnosis of Iron Deficiency, Iron Deficiency Anemia, and the Underlying Cause

Hemoglobin, the most commonly used screening test for IDA, is limited by the fact that anemia does not occur until there is marked depletion of storage iron and progression of iron-restricted erythropoiesis. Serum ferritin is limited as a measure of iron stores by the fact that it is an acute phase reactant. Although sTfR is a marker of tissue iron deficiency, it is not decreased until there is substantial iron-restricted erythropoiesis. Thus, in the absence of inflammation, in healthy populations in high-resource countries with low incidence of IDA, serum ferritin remains the most useful screening test for iron deficiency without anemia. Microcytic anemia can result from a number of causes, and every effort must be made to establish or exclude the diagnosis of IDA as well as to determine the underlying cause. Because no single clinical finding or laboratory test is diagnostic of iron deficiency, a combination of all available clinical findings and laboratory data must be taken into consideration to establish the diagnosis. The sTfR can distinguish between IDA and functional iron deficiency caused by inflammation. The CHr can distinguish between IDA and anemia related to hemoglobinopathy trait.

## MANAGEMENT

### Therapeutic Trial of Iron

Therapeutic trial of iron has been proposed as a convenient method to diagnose iron deficiency in patients with anemia. Although this is a reasonable approach in otherwise healthy individuals, in those at high risk for deficiency, such as infants, teenage girls, and pregnant women, it is better to make a definitive laboratory diagnosis at the outset. Further, this approach requires good follow-up and good adherence with

medication intake, which may not be the case in many situations in which IDA is suspected.

### Treatment of Iron Deficiency

The treatment of choice for iron deficiency is the oral administration of iron. Although various iron salts are available, ferrous sulfate is inexpensive and well tolerated, although there may be adverse effects such as nausea, dyspepsia, constipation, and diarrhea. Adverse effects can be managed by administering the iron with or immediately after meals. If symptoms persist, reducing the amount of iron in each dose or reducing the frequency to a single daily dose may help control the side effects. If there is persistent intolerance, switching to ferrous gluconate may be helpful. Iron polysaccharide complex also has the advantage of being available as tablets or elixir and is well tolerated. About twice as much iron is absorbed on an empty stomach as at mealtime. Milk consumption should be limited to allow increased intake of iron-rich foods, and to reduce blood loss from intolerance to cow milk proteins.

Because soy-based formulas can also lead to blood loss, children with milk enteropathy should be switched to a primary diet of iron-containing solids or an extensively hydrolyzed formula or an amino acid–based formula. In the absence of ongoing blood losses, response to iron therapy is rapid and predictable (Figure 279-1). A response with decreased irritability and increased appetite to oral iron therapy has been noted within 12 to 24 hours (Table 279-5). The reticulocyte response peaks at 5 to 7 days after iron therapy. In an otherwise healthy individual, the recovery from anemia is about two-thirds complete within 1 month. The hemoglobin should be measured again at 1 month to check the therapeutic progress and to emphasize compliance.

If after 4 weeks the anemia does not respond to iron treatment despite compliance with the iron supplementation regimen and the absence of acute illness, the anemia can be further evaluated by using other laboratory tests, including MCV, RDW, and serum ferritin concentration. After the diagnosis of iron deficiency is confirmed, either by a response to a therapeutic trial or by further laboratory tests, oral therapy with elemental iron at 3 to 6 mg/kg per day should be continued for 2 to 3 months after normal hemoglobin levels are restored. This allows the repletion of body iron stores. Anemia, microcytosis, and increased FEP levels are corrected completely with 3 to 5 months of treatment.

### **BOX 279-1 Recommendations for the Diagnosis and Prevention of Iron Deficiency in Infants, Young Children, and Adolescents**

#### **BREASTFEEDING AND IRON-FORTIFIED FORMULA**

- Full-term, healthy infants are at increased risk for iron deficiency after 4 months. Exclusively breastfed or partially breastfed infants should be started on an oral iron preparation at 1 mg/kg/day at age 4 months to be continued until the introduction of iron-containing complementary foods, red meats, or vegetables with high iron content.
- The iron needs of formula-fed infants can be met by standard formula and complementary foods, including iron-fortified cereal introduced after age 4 to 6 months.
- Whole milk should not be introduced before age 12 months.
- Infants 6 to 12 months of age should receive 11 mg iron/day.
- Complementary foods, red meats, and iron-rich vegetables should be introduced early. If their intake is not meeting iron requirements, an oral iron preparation at 1 mg/kg/day should be given.
- Toddlers 1 to 3 years of age should receive a daily iron intake of 7 mg through iron-fortified cereals, red meats, and iron-rich vegetables. If iron requirements are not being met, they should receive an oral iron preparation at 1 mg/kg/day.
- Beyond 3 years of age, children may receive chewable multivitamins.
- Preterm infants require 2 mg/kg/day of iron starting at age 1 month through when they are weaned to an iron-fortified formula or complementary food that can provide the daily iron requirement of 2 mg/kg/day.

#### **SOLID FOODS**

- At age 4 to 6 months or when the extrusion reflex disappears, recommend that infants be introduced to plain, iron-fortified infant cereal. Two or more servings per day of iron-fortified infant cereal can meet the requirement for iron at this age.
- By approximately age 6 months, encourage 1 feeding per day of foods rich in vitamin C (eg, fruits, vegetables, juice) to improve iron absorption, preferably with meals.
- Suggest introducing plain, pureed meats after age 6 months or when the infant is developmentally ready to consume such food.

#### **ADOLESCENT GIRLS AND NONPREGNANT WOMEN**

- Encourage adolescent girls and women to eat iron-rich foods and foods that enhance iron absorption and to optimize their dietary iron intake.

From Centers for Disease Control and Prevention. Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep*. 1998; 47(RR-3):1–29; Baker RD, Greer FR, American Academy of Pediatrics Committee on Nutrition. Diagnosis and prevention of iron deficiency and iron-deficiency anemia in infants and young children (0–3 years of age). *Pediatrics*. 2010;126(5):1040–1050.

Systematic reviews and meta-analyses of the literature have not revealed intravenous iron infusions to be associated with severe adverse events or increased risk for infections as was previously suspected. With the exception of high-molecular-weight dextran preparations, iron infusions have been found to be safe and only associated with infusional reactions, which may in fact be related to premedication administered. The availability of new intravenous iron formulations with an improved safety profile and ease of administration has expanded the option of this route of iron administration in select populations. Iron sucrose and ferric gluconate can be used to administer a total dose of iron in 1-hour infusions. New iron preparations such as ferumoxytol bind iron more avidly, thus reducing the risk of release of labile iron during infusions. Large single doses can be administered safely in as little as 15 minutes. Intravenous iron preparations have hitherto been reserved for conditions such as chronic kidney disease and failure of iron absorption caused by inflammatory bowel disease or bariatric or other gastrointestinal surgery. Improved ease of administration and lack of side effects are expanding the consideration of this treatment to other conditions.

A blood transfusion is indicated only when severe anemia leads to congestive heart failure and cardiovascular compromise. If a blood transfusion is clinically

warranted, then packed RBCs should be given slowly or a partial exchange transfusion performed. Vital signs should be monitored carefully.

#### **Failure to Respond to Therapy**

When a patient fails to respond to oral iron treatment, the following factors should be considered: (1) non-compliance with oral therapy; (2) inadequate iron dose; (3) persistent or unrecognized blood loss; (4) malabsorption of iron (eg, primary gastrointestinal disease); (5) other diagnoses (eg,  $\alpha$ - or  $\beta$ -thalassemia trait and hemoglobin E disease); and (6) poor iron utilization (eg, chronic inflammatory disease, sideroblastic anemia, lead poisoning, and congenital atransferrinemia).

#### **PREVENTION**

Increased iron intake among infants has reduced childhood IDA in the United States. Consequently, the use of screening tests for anemia has become a less efficient means of detecting iron deficiency in some populations, whereas for women of childbearing age, iron deficiency has remained prevalent. Recommendations are provided for primary prevention of iron deficiency through appropriate dietary intake (Box 279-1), and secondary prevention through detecting and treating IDA (Box 279-2).

**BOX 279-2 Recommendations for Screening for Iron Deficiency in Infants, Children, and Adolescents**

- Universal screening for iron deficiency should occur at age 12 months and 6 months later and should include evaluation of hemoglobin and risk factors for iron deficiency, such as
  - Preterm or low-birth-weight infants
  - Infants fed a diet of non-iron-fortified infant formula for >2 months
  - Infants introduced to milk before age 12 months
  - Breastfed infants who do not consume a diet adequate in iron after age 6 months (ie, who receive insufficient iron from supplementary foods)
  - Children who consume >24 oz daily of cow milk
  - Children who have special health care needs (eg, children who use medications that interfere with iron absorption and children who have chronic infection, inflammatory disorders, restricted diets, or extensive blood loss from a wound, an accident, or surgery)
- If, at 12 months of age, hemoglobin is <11 g/dL, additional evaluation for iron-deficiency anemia (IDA) should be undertaken. Potentially useful tests include ferritin, transferrin saturation, soluble transferrin receptor with C-reactive protein, or reticulocyte hemoglobin concentration.
- In cases of mild anemia (hemoglobin 10–11 g/dL), an alternative diagnostic approach would be to document an increase of hemoglobin by at least 1 g/dL following 1 month of appropriate therapeutic doses of an oral iron preparation.
- Annual assessment of children ages 2 to 5 years for risk factors for IDA (eg, a low-iron diet, limited access to food because of poverty or neglect, special health care needs).
- In populations of infants and preschool-aged children at high risk for IDA (eg, children from low-income families, children eligible for the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), migrant children, or recently arrived refugee children), screen for anemia between ages 9 and 12 months, 6 months later, and annually from ages 2 to 5 years.
- Starting in adolescence, screen all nonpregnant women for anemia every 5 to 10 years throughout their childbearing years during routine health examinations.
- Annually screen for anemia women having risk factors for iron deficiency (eg, extensive menstrual or other blood loss, low iron intake, a previous diagnosis of IDA).

From Centers for Disease Control and Prevention. Recommendations to prevent and control iron deficiency in the United States. *MMWR Recomm Rep*. 1998;47:1–29; Baker RD, Greer FR; American Academy of Pediatrics Committee on Nutrition. Diagnosis and prevention of iron deficiency and iron-deficiency anemia in infants and young children (0–3 years of age). *Pediatrics*. 2010;126(5):1040–1050.

**WHEN TO REFER**

- Cause of anemia is unknown.
- Gastrointestinal blood loss is suspected.
- Anemia is not explained by nutritional imbalance.
- Anemia is refractory to treatment.
- Child requires intravenous iron.
- Diagnosis of iron deficiency is questionable.

**WHEN TO ADMIT**

- Child exhibits signs of cardiac failure.
- Child requires intravenous iron.
- Child has moderate to severe blood loss.

## Chapter 280

# KAWASAKI DISEASE

Mary Anne Jackson, MD

Kawasaki disease is an acute, multisystem vasculitis of infancy and early childhood characterized by high fever, rash (Figure 280-1), conjunctivitis (Figure 280-2), inflammation of the mucous membranes (Figure 280-3), erythematous induration of the hands and feet, and unilateral cervical adenopathy. Formerly known as *mucocutaneous lymph node syndrome*, Kawasaki disease is the main cause of acquired heart disease in children in the developed world. It was first described in 1967 by a Japanese pediatrician, Tomisaku Kawasaki; in 1974 the first cases of Kawasaki disease were reported in the United States. In retrospect, illnesses that are similar to Kawasaki disease were described as early as 1871. Landing and Larson compared the features of Kawasaki disease with infantile periarteritis nodosa and found that the 2 conditions shared many clinical signs and had indistinguishable pathologic findings.

### EPIDEMIOLOGIC FEATURES

The peak age incidence of Kawasaki disease occurs during the second year of life. More than 80% of all cases occur in children younger than 5 years; the disease is uncommon beyond 9 years of age, but cases in older children clearly occur. Boys are more commonly affected than girls, with a male-to-female ratio of nearly 1.5:1. Now, Kawasaki disease is recognized as having a worldwide distribution, although it is most prevalent in Japan and in children of Japanese ancestry. The Centers for Disease Control and Prevention estimate that the incidence for children 8 years or younger in the continental United States is 32.5 cases per 100,000 in those of Asian or part Asian descent, 16.9 per 100,000 in blacks,

11.1 per 100,000 in Hispanics, and 9.1 per 100,000 in whites. Kawasaki disease occurs more commonly in winter and spring, and numerous temporal clusters have been reported in the United States and Japan.

Recurrent cases of Kawasaki disease have been reported in the United States and Japan, with rates ranging from 0.3% to 5% in Japan and 1% to 2% in the United States.

### ETIOLOGY

No established cause for Kawasaki disease has been found, although clinical and epidemiologic features suggest an infectious process.

### PATHOGENESIS

Kawasaki disease is associated with increased production of cytokines by T cells and monocytes, and this feature is thought to play an important role in the pathogenesis of vascular endothelial cell injury during acute Kawasaki disease because these cytokines elicit proinflammatory and prothrombic responses in endothelial cells. Cytokines and chemokines have been

**Figure 280-2** Child with Kawasaki disease with conjunctivitis. Note the absence of conjunctival discharge. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org).)

**Figure 280-1** Characteristic distribution of erythroderma of Kawasaki disease. The rash is accentuated in the perineal area in approximately two-thirds of children. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org).)

**Figure 280-3** Child with Kawasaki disease with striking facial rash and erythema of the oral mucous membrane. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org).)

detected in tissue obtained from patients in the acute stage of Kawasaki disease. More recent data suggest 3 components to the arteriopathy that characterizes Kawasaki disease. Within the early clinical phase, a necrotizing neutrophilic vasculitis predominates and may lead to coronary damage manifest as dilation or aneurysm formation. This is followed in the subacute phase by lymphocytic, plasma cell and eosinophilic vascular infiltration. In the late phase, myofibroblastic proliferation can lead to vascular stenosis.

## DIFFERENTIAL DIAGNOSIS

The clinical picture of Kawasaki disease, after all major features have exhibited, is generally not difficult to differentiate from other mucocutaneous syndromes, although diagnostic challenges may occur in cases in which the patient is very young or has an unusual or incomplete presentation. In the first days of the illness, a whole spectrum of acute febrile diseases might be considered. Three to 5 days after the onset, certain clinical features may be singled out as compatible with other diagnoses, for example, strawberry tongue, which is suggestive of streptococcal infection. The 2 conditions that most commonly mimic Kawasaki disease are streptococcal and staphylococcal exfoliative toxin syndrome. However, if all the signs and symptoms are considered carefully, then the diagnosis is more readily apparent. The clinical features of Kawasaki disease and other mucocutaneous disorders are shown in Table 280-1. Other conditions that share some aspects of Kawasaki disease are rubella, rubeola, infectious mononucleosis, other viral exanthems, juvenile rheumatoid arthritis, and febrile drug reactions or Stevens Johnson syndrome (eg, anticonvulsants or trimethoprim with sulfamethoxazole). The similarities between fatal Kawasaki disease and fatal infantile polyarteritis nodosa are striking; pathologically, the 2 diseases cannot be distinguished. However, the exact relationship between them is undetermined.

## CLINICAL MANIFESTATIONS

To make the diagnosis of typical Kawasaki disease, 5 of the 6 major clinical characteristics associated with the condition must be present (Box 280-1). Illnesses having similar features should be considered. The detection of common respiratory viral pathogens (eg, rhinovirus, human metapneumovirus, parainfluenza virus, influenza virus) does not exclude Kawasaki disease. Symptoms vary in severity, but more than 90% of patients fulfill the first 5 clinical criteria. All of the symptoms are not apparent simultaneously, but the timing of their appearance is remarkably constant.

The course of the disease can best be described as triphasic. The acute phase consists of fever, conjunctival hyperemia, oropharyngeal erythema, lip cracking and fissuring, swelling of the hands and feet, a polymorphous erythematous rash, and unilateral cervical lymphadenopathy. Fever, rash, and lymphadenopathy fade after 10 to 12 days of the illness, marking the beginning of the subacute phase when arthralgias or arthritis (or both) and desquamation of skin overlying the tips of the fingers and toes, thrombocytosis, and cardiac disease may occur. The convalescent stage usually begins approximately 25 days after onset and

is characterized by the absence of clinical signs of disease but with the persistence of residual inflammation, marked by an elevated erythrocyte sedimentation rate (ESR).

Fever is the most prominent symptom of the acute phase of the disease. Temperatures show a high-spiking remittent pattern in the range of 38.4°C (101.1°F) to higher than 40°C (104°F). Fever persists despite the use of empirical antibiotics and standard doses of antipyretics. Fever is present on average for approximately 12 days, although prolonged courses of up to 5 weeks have been reported; defervescence occurs over 1 to 3 days. Discrete engorgement of the bulbar conjunctivae blood vessels (without associated discharge, exudate, keratitis, chemosis, or pseudomembrane formation) and an anterior uveitis develop shortly after the onset of fever but are usually resolved after 7 days. The cornea, lens, and retina are not involved. Early oropharyngeal signs include dryness and reddening of the lips and of the buccal and pharyngeal mucosa. The absence of aphthous ulceration or hemorrhagic bullae is noticeable. A strawberry tongue is frequently present. Later, as the intensity of the erythema subsides, the lips usually become cracked and fissured.

The most characteristic and unique feature of Kawasaki disease relates to changes that occur in the hands and feet. Early on, they become diffusely indurated and swollen, and the overlying skin develops a woody firmness suggestive of acute scleroderma. The palms and soles usually become erythematous or take on a purplish hue. Fusiform swelling of the fingers also occurs, which limits the child's ability to grasp objects. The feet are painful to the touch, and many children will refuse to stand or walk. Two to 3 weeks after the onset of illness and after the early signs involving the extremities have disappeared, an unusual desquamation of the skin beginning at the subungual and periungual regions of the fingers and toes occurs in nearly all cases (Figure 280-4). Progression to complete peeling of the palms and soles may occur, but exfoliation generally does not extend to the remainder of the body surface. During the convalescent phase, deep transverse grooves (Beau lines) may appear across the fingernails and toenails, presumably as a result of arrested growth during the illness.

A polymorphous, erythematous rash appears 1 to 5 days after the onset of fever; it usually begins on the extremities and spreads centripetally. The 3 most common patterns of rash are maculopapular (morbilliform), erythema multiforme-like with iris lesions, and scarlatiniform.

The rash may be coalescent, producing large, irregular, raised plaques, and it may be pruritic. Vesicles, pustules, and bullae are not seen. The rash is not petechial or purpuric and typically does not involve the face. It usually fades within 1 week but occasionally persists longer or recurs.

Lymphadenopathy typically involves a single cervical node measuring more than 1.5 cm in diameter. The node is usually not tender or warm and does not become fluctuant. Generalized lymphadenopathy does not occur. The lymph node diminishes in size with defervescence of the disease. Lymphadenopathy is the least often seen of the major criteria; it occurs in only

### BOX 280-1 Diagnostic Criteria for Kawasaki Disease

#### PRINCIPAL SYMPTOMS

Fever of unknown cause lasting  $\geq 5$  days and at least 4 of the following 5 symptoms:

- Bilateral congestion of ocular bulbar nonexudative conjunctivae with limbic sparing
- Changes of lips (fissuring, redness) and oral cavity (erythema of mucosa, strawberry tongue)
- Polymorphous rash without vesicles or crust
- Unilateral nonsuppurative lymphadenopathy measuring  $>1.5$  cm
- Changes of the peripheral extremities (indurative edema, reddened palms and soles; late periungual desquamation)

#### OTHER SIGNIFICANT SYMPTOMS OR FINDINGS

- Carditis, especially myocarditis or pericarditis
- Diarrhea
- Arthralgia or arthritis
- Proteinuria and increase of leukocytes in urine sediment

#### CHANGES IN BLOOD TESTS

- Leukocytosis with shift to the left
- Slight decrease in erythrocyte and hemoglobin levels
- Increased sedimentation rate
- Elevated C-reactive protein
- Thrombocytosis in convalescent phase

#### CHANGES OCCASIONALLY OBSERVED

- Aseptic meningitis
- Mild jaundice or slight increase of serum transaminase
- Hydrops of gallbladder

approximately 60% of patients in most US series. Occasionally, lymphadenopathy is the heralding of Kawasaki disease and has been noted usually in boys older than 5 years. In some cases, retropharyngeal phlegmon is present. In cases in which lymph node only is noted at onset, other features of Kawasaki disease may follow.

In addition to the 6 major clinical signs, other features of Kawasaki disease are frequently noted. Irritability, mild meningismus, and lethargy are seen in nearly all of these children. Diarrhea is seen in approximately 50% of the children. Passing 5 to 15 stools per day for 2 to 7 days during the acute or subacute phase is common. Stools do not contain polymorphonuclear cells and do not test positive for occult blood.

Either arthralgias, arthritis, or both occur in 30% to 40% of children. Large joints, particularly the knees and ankles, are involved most often. Usually, no more than 2 or 3 joints will be affected. Joint symptoms occur 8 to 12 days after the onset of disease. Joint fluid, if analyzed, will reveal findings similar to those of rheumatoid arthritis.

Pneumonia, tympanitis, and photophobia are observed somewhat less commonly. Acute hydrops of

**Figure 280-4** Desquamation of the skin involving the subungual and periungual regions of the fingertips. (Courtesy Red Book Online. [redbook.solutions.aap.org](http://redbook.solutions.aap.org).)

the gallbladder, jaundice, convulsions, encephalopathy, Bell palsy, hearing loss, pancreatitis, orchitis, and pleural effusions are rarely seen but are clearly associated features of Kawasaki disease. In addition, a small subset of patients can present with hypotensive shock.

The most critical complications of Kawasaki disease are those in the cardiovascular system. If untreated, up to 25% of patients will develop coronary artery involvement, with some developing coronary aneurysms. The mortality of the disease is the result of coronary artery aneurysm rupture or occlusion. During the acute phase, tachycardia and gallop rhythms may appear; however, the most serious manifestations of cardiac involvement occur during the subacute phase. These manifestations include serious arrhythmias, congestive heart failure, pericardial effusion, mitral insufficiency, and myocardial ischemia or infarction.

### LABORATORY FINDINGS

Although Kawasaki disease has no pathognomonic laboratory findings, certain laboratory abnormalities are frequently seen and therefore help establish the diagnosis. Either erythrocyte sedimentation rate  $>40$  mm or C-reactive protein  $>3$  mL/dl are present in virtually all cases. In the acute phase of the disease, most patients exhibit an elevated white blood cell (WBC) count with an associated left shift; WBC counts of 15,000 to 20,000/mm<sup>3</sup> are common and may remain elevated for 1 to 3 weeks; normocytic, normocytic anemia for age may occur. Sterile pyuria occurs in 70%; 10 to 100 WBCs per high-power field may be observed on a clean-catch voided urine specimen. No WBCs will be seen on a bladder aspiration specimen because the sterile pyuria is caused by urethral inflammation or ulceration. Occasionally, a child will demonstrate trace proteinuria or hematuria. Mild transaminitis may occur in 50% of cases. If cerebrospinal fluid (CSF) is analyzed, it typically shows 25 to 100 WBCs/mm<sup>3</sup> with normal amounts of glucose and protein. In addition, elevated serum bilirubin, hypoalbuminemia,

thrombocytopenia early on, and hyponatremia can be seen. Low albumin, anemia, and thrombocytopenia are poor prognostic factors.

In the second to third week of the illness, patients characteristically develop significant thrombocytosis, with platelet counts averaging in excess of 700,000/mm<sup>3</sup>. Importantly, the results of several laboratory studies are negative. Routine cultures of blood, CSF, urine, throat, and lymph node aspirates reveal no growth or normal flora. Serologic studies for bacterial and viral agents are negative, including the antistreptolysin titer. Antinuclear antibodies, rheumatoid factor, and other autoantibodies are absent. The detection of a common respiratory virus-like parainfluenza, influenza, rhinovirus, or human metapneumovirus does not exclude the diagnosis in a child who otherwise meets criteria for Kawasaki disease. A diagnostic challenge may be posed in the child with fever and exudative pharyngitis related to adenovirus infection. In such cases, if adenovirus is confirmed by detection of adenovirus in a nasopharyngeal swab, the diagnosis of Kawasaki disease is considered unlikely. Consultation with a pediatrician who has expertise in the diagnosis of Kawasaki disease should be sought in such cases.

Sinus tachycardia, nonspecific ST segment and T wave changes, and evidence of mild left ventricular hypertrophy may be seen on an electrocardiogram in the acute phase.

A baseline echocardiogram should be performed as soon as the diagnosis of Kawasaki disease is suspected to evaluate cardiac function and the anatomy of the coronary arteries and to assess for the presence or absence of pericardial effusion. However, in most cases, the baseline echocardiogram is normal and does not exclude the diagnosis. Coronary artery abnormalities may develop as early as 5 to 7 days after onset of illness but are generally apparent by the third or fourth week of the illness. The findings in incomplete Kawasaki disease are listed in Box 280-2. Coronary artery disease rarely, if ever, develops after 6 to 8 weeks.

Severe or even fatal coronary abnormalities can develop after illnesses that resemble but do not fulfill the classic diagnostic features of Kawasaki disease. Important aspects of incomplete Kawasaki disease are listed in Box 280-3. Children who have incomplete Kawasaki disease may display prolonged high fever, nonspecific rash, arthralgia or arthritis, fissuring of the lips, nonexudative conjunctivitis, and extreme irritability. An algorithm for evaluating suspected incomplete Kawasaki disease is shown in Figure 280-5. In infants younger than 6 months, Kawasaki disease may present solely with prolonged fever or is likely to produce subtle manifestations (Box 280-4); this group is at highest risk ( $\geq 50\%$ ) for coronary artery lesions if untreated.

## MANAGEMENT

Intravenous immunoglobulin (IVIG) with aspirin is the best available therapy for preventing coronary artery abnormalities in Kawasaki disease and should be administered to all patients diagnosed within the first 10 days of the illness. Physicians should institute treatment as soon as the diagnosis is established and as

### BOX 280-2 Echocardiogram

- Should be performed at baseline in all cases of suspected Kawasaki disease. A normal study does not exclude the diagnosis.
- Should be performed in follow-up of all children treated for Kawasaki disease and in those who present with classic periungual desquamation in cases in which the diagnosis was missed.
- Useful in evaluating children with prolonged fever and some features of Kawasaki disease.
- Although aneurysms rarely form before day 10 of the illness, ectasia of the coronary arteries can be seen in the acute stage of disease.
- Other findings
  - Decreased left ventricular contractility
  - Mild valvular regurgitation (mitral regurgitation)
  - Pericardial effusion

From Newberger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics*. 2004;114(6):1708–1733.

### BOX 280-3 Unusual Clinical Manifestations of Kawasaki Disease

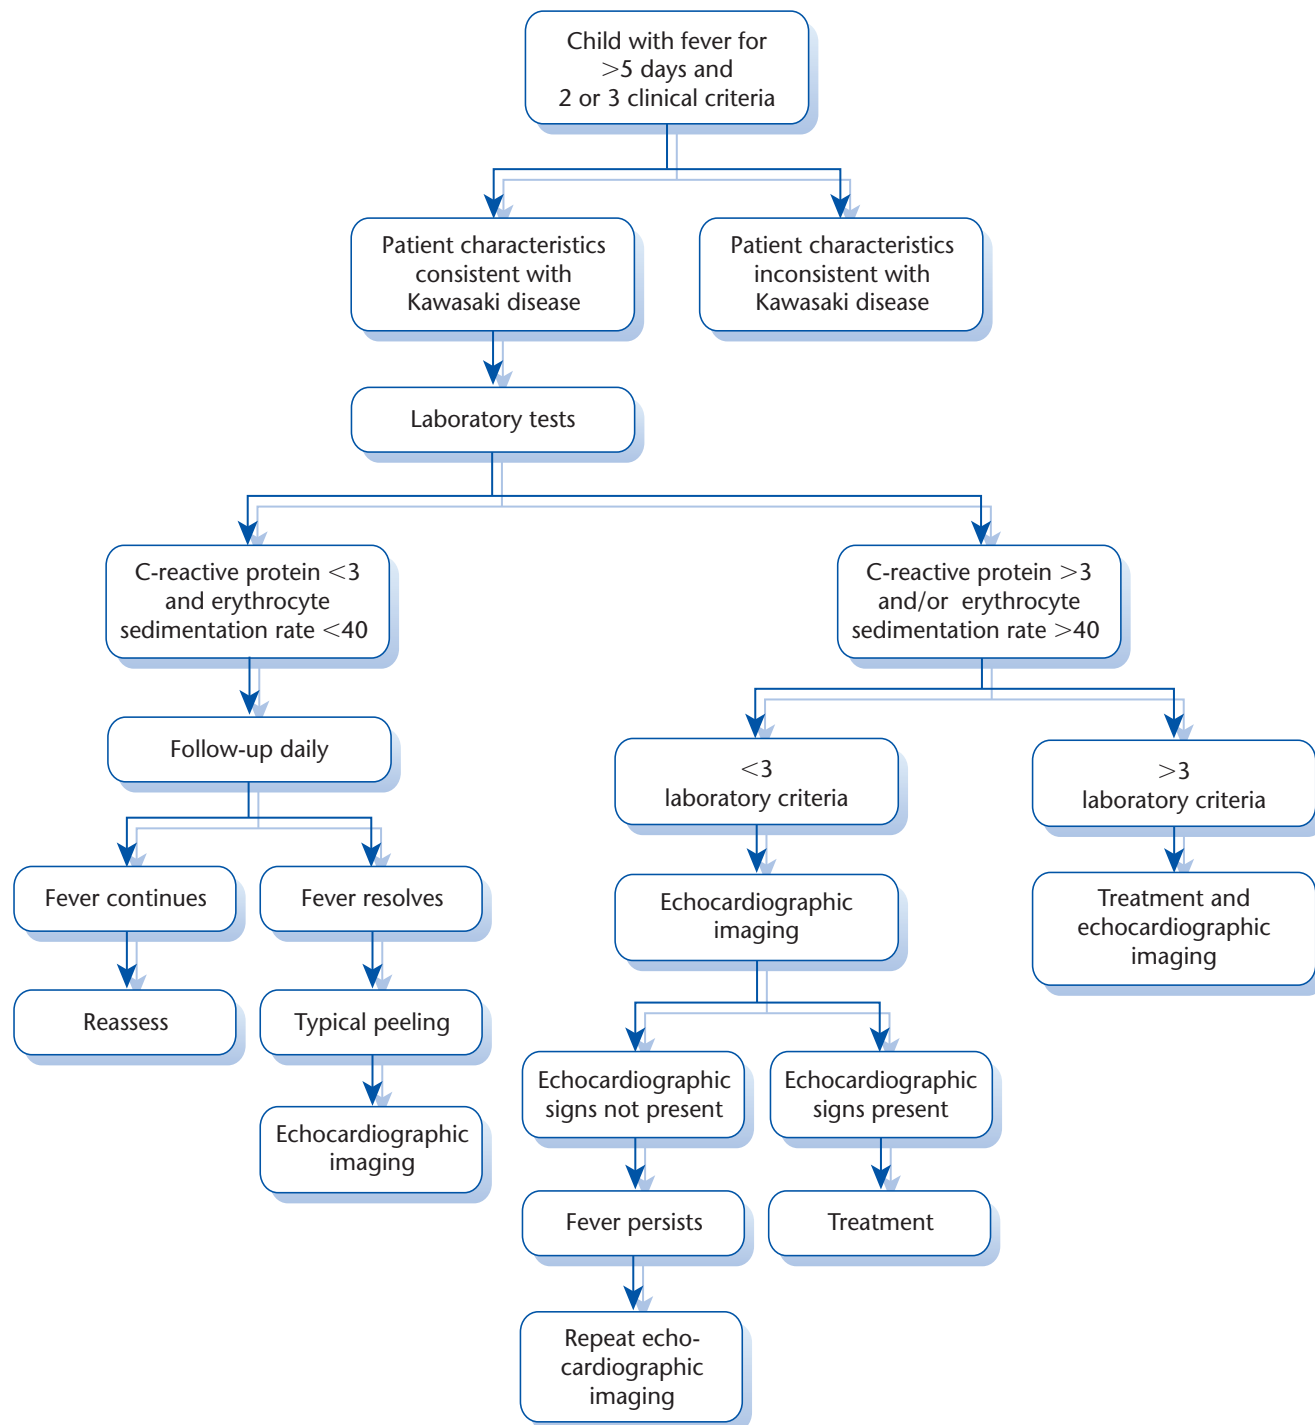

- Consider Kawasaki disease in infants and children with unexplained fever for  $> 5$  days and 2 or 3 of the principal diagnostic criteria.
- Young infants may have fever only.
- Laboratory results are similar to those of classic cases.
- A shock presentation may be seen and mimic bacterial sepsis.
- A lymph node first presentation may occur, often in boys, and may mimic bacterial lymphadenitis. Usually more typical features of Kawasaki disease follow the initial presentation, and laboratory features are consistent with Kawasaki disease.

From Newberger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics*. 2004;114(6):1708–1733.

early as possible in the course of the illness. Aspirin, given in high doses (80 mg/kg/day) every 6 hours, reduces the length and severity of Kawasaki disease during the acute phase. Aspirin use early in the course of the disease may also reduce coronary artery involvement. Dosages should be reduced to 3 to 5 mg/kg/day after the child has been afebrile for 48 to 72 hours. If coronary aneurysms are recognized, then salicylates (3 to 5 mg/kg/day) should be continued long term with careful cardiology follow-up and discontinuation with aneurysm resolution.

High-dose IVIG is effective to prevent coronary artery lesions in Kawasaki disease. A single dose of 2 g/kg is infused over 10 to 12 hours. No apparent

**Figure 280-5** Evaluation of suspected incomplete Kawasaki Disease. (From Newberger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics*. 2004;114[6]:1708–1733.)

difference exists in efficacy among particular IVIG products currently commercially available. Children should be monitored carefully during IVIG infusions for signs of anaphylaxis and immune hemolysis. Eighty percent to 90% of children treated with IVIG respond favorably with decreased fever and reduced

mucocutaneous findings. The remainder has persistent or recurrent fever, with or without mucocutaneous signs. If ongoing fever cannot be attributed to another cause, then the assumption should be made that Kawasaki disease is persisting or has relapsed. Because fever may be viewed as a sign of continued

**BOX 280-4 Kawasaki Disease in Infants Younger Than 6 Months**

- These infants usually lack full diagnostic criteria.
- Manifestations are often subtle: fever, rash, and cerebrospinal fluid pleocytosis may be misdiagnosed as viral meningitis. Inflammatory markers are routinely elevated.
- These infants have high risk for coronary abnormalities.
- Echocardiography should be performed.

From Newberger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics*. 2004;114(6):1708–1733.

vasculitis, retreatment with IVIG is advocated. Most patients treated again after a single dose of IVIG therapy has failed will respond to retreatment. Patients who remain symptomatic beyond the tenth day may still benefit from IVIG. However, the decision to administer IVIG later than the tenth day of the illness must be individualized. The timing of retreatment is important: retreatment with IVIG is recommended if fever recurs or persists 36 hours after the end of the first IVIG infusion.

If therapy fails (particularly after 2 treatments), pulse doses of methyl prednisolone at 30 mg/kg per dose for 1 to 3 days or infliximab 5 mg/kg as a single infusion should be administered. This therapy should be reserved for children who are clearly refractory to other, more established treatments (ie, failure of 2 doses of IVIG). Antibiotics are not indicated. It is important to counsel parents and pediatricians that live vaccines must be delayed for 11 months after IVIG and on the signs and symptoms of Reye syndrome while on aspirin therapy.

## COMPLICATIONS

The major complication of Kawasaki disease is the development of coronary artery aneurysms. If IVIG is not administered, then aneurysms occur in 15% to 25% of cases and are usually apparent by echocardiogram during the subacute phase of the illness. Coronary artery abnormalities can also be seen in 2% to 4% of cases, despite appropriate early therapy. Most patients who have aneurysms are asymptomatic; however, in some cases, formation of an aneurysm, particularly a giant aneurysm ( $>8$  mm in diameter), is followed by thrombosis or rupture, resulting in a fatal myocardial infarction. The care of a child with coronary involvement should always include consultation with a pediatric cardiologist experienced in management of Kawasaki disease. Treatment of moderately large aneurysms may require anticoagulation with clopidogrel (1 mg/kg/day) in combination with low-dose aspirin. For those with giant (or in young infants with an increase in coronary artery size  $>6$  mm), anticoagulant therapy with warfarin or low-molecular-weight heparin is required. The indication for and timing of angiography is controversial. Percutaneous

transluminal coronary angioplasty has been attempted by several groups with mixed results.

For long-term management of patients with Kawasaki disease, a risk stratification scheme may be of benefit (Table 280-2). For children at level I risk, the primary care physician may fully assume care after the first year anniversary of Kawasaki disease onset. Physical activities should not be restricted. For children with level II risk, a pediatric cardiologist should be consulted every 1 to 2 years; at least 1 stress test evaluating myocardial functioning should be performed at approximately 10 years of age. For children in risk level III, daily low-dose aspirin therapy and annual cardiac follow-up with echocardiography and electrocardiography may be appropriate. Periodic stress tests are recommended. For children in risk level IV, low-dose aspirin therapy should be maintained, and low-dose warfarin should be considered. Coronary angiography may be considered 6 to 12 months after the acute disease resolves to delineate coronary artery anatomy. Physical activities should be modified to minimize the risk for hemorrhage. Strenuous or competitive sports should be avoided. Children at risk level V should receive daily low-dose aspirin, and warfarin should be considered. Patients should be evaluated for indications of bypass graft surgery.

The coronary artery aneurysms seen in Kawasaki disease develop more frequently in boys than they do in girls, in children younger than 1 year, and in those who have a triphasic fever pattern or fever for longer than 2 weeks when a gallop rhythm or other arrhythmia is noted or when the ESR exceeds 50 mm/hr (Box 280-5). Cases of incomplete Kawasaki Disease followed by typical coronary artery involvement have led to the suggestion that an echocardiography examination be undertaken in children who have prolonged unexplained febrile illnesses associated with subsequent peripheral desquamation.

## PROGNOSIS

Kawasaki disease has a 0.2% mortality rate. Death occurs almost exclusively in children who have giant aneurysms, mainly as a result of coronary artery thrombosis, massive myocardial infarction, and cardiogenic shock. Eighty percent of children whose aneurysms are small to moderate in size have complete resolution without apparent sequelae within 5 years. The remaining children may experience persisting aneurysms, coronary artery stenosis or obstruction, or aortic regurgitation. Emerging evidence suggests that a portion of this last group of children may be at risk for the subsequent development of significant cardiovascular disease such as coronary arteriosclerosis or persistent aneurysms, placing some of them at risk for sudden death from aneurysm rupture or thrombosis, cardiac arrhythmias, angina, or hypertension.

## PSYCHOSOCIAL ASPECTS

Kawasaki disease is almost always a self-limited illness without complications, which should be emphasized to the parents. Recurrent disease occurs months to years later in 2% of cases.

Even if coronary artery aneurysms do develop, they resolve spontaneously in more than 50% of cases

**Table 280-2****Levels of Risk for Determination of Methods for Management of Kawasaki Disease–Induced Coronary Artery Disease**

RISK LEVEL	DESCRIPTION
I	No coronary artery abnormalities at any stage of the illness
II	Transient coronary artery ectasia followed by regression
III	Small to medium solitary coronary artery aneurysm
IV	One or more giant aneurysms or multiple aneurysms without obstruction
V	Coronary artery obstruction (thrombosis or stenosis)

From Newberger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics*. 2004;114(6):1708–1733.

**BOX 280-5 Risk Factors for Coronary Artery Aneurysms in Kawasaki Disease**

- Missed or delayed diagnosis including fever lasts >14 days
- Boys
- Extremes of age (<6 months, >9 years)
- Asian or Pacific Islander, Hispanic children
- Recurrent Kawasaki disease

within 2 years and 80% within 5 years. Long-term risks still remain undefined, and only as physicians gain prospective experience with the disease over several more decades will the true incidence of cardiovascular sequelae become evident.

**Chapter 281****KLINEFELTER SYNDROME**

Parul Jayakar, MD; Michail Spiliopoulos, MD

**DEFINITION**

Klinefelter syndrome describes a group of disorders characterized by the presence of at least 1 extra X chromosome in a male. Approximately 80% of cases are caused by 1 extra X chromosome with karyotype 47,XXY (see Figure 281-1). The original series of 9 patients was described by Klinefelter in 1942, but the karyotypic abnormality was not discovered until 1959 by Jacobs and Strong. As more patients with the syndrome were tested, other chromosomal aneuploidies were noted in 20% of them, such as 48,XXXY; 48,XXYY and 49,XXXXY. Mosaics like 46,XY/47,XXY and patients with structurally abnormal X chromosomes were also found.

The typical patient with Klinefelter syndrome has been described as tall with long limbs, narrow shoulders, sparse hair, small penis and testes with azoospermia and gynecomastia. Infertility is very common, as are difficulties in expressive language and reading. Despite this “typical” phenotype, many patients with very subtle clinical features remain undiagnosed for several years. The findings of a national registry study

**Figure 281-1** Klinefelter syndrome karyotype. (From Lanfranco F, Kamischke A, Zitzmann M, Nieschlag E. Klinefelter syndrome. *Lancet*. 2004;364:273–283, with permission from Elsevier.)

from Denmark showed a high degree of underdiagnosis of Klinefelter syndrome, with less than 10% of the patients diagnosed before puberty.

## EPIDEMIOLOGY

Aneuploidy for XXY is considered to be the most common sex chromosomal abnormality and has a prevalence of approximately 1 in 500 males. Approximately 250,000 men in the United States have Klinefelter syndrome, although most of them are never diagnosed. The presence of other sex chromosomal abnormalities resulting in Klinefelter syndrome is much less frequent. More specifically, 48,XXYY and 48,XXXY are present in approximately 1 in 17,000 to 1 in 50,000 births. Even more rare is 49,XXXXY, which has an incidence of 1 in 85,000 to 1 in 100,000 male births. The actual prevalence of Klinefelter syndrome could be underestimated because of bias present in most studies from a high degree of underdiagnosis.

## ETIOLOGY AND PATHOGENESIS

The aberrations in the number of sex chromosomes occurring in Klinefelter syndrome are caused by

nondisjunction, most commonly during paternal meiosis I. This mechanism accounts for approximately 50% of the cases, with the rest of them attributed to errors in maternal meiosis I, or maternal meiosis II. Paternal errors can only occur during meiosis I, because this is the only mechanism that can produce a gamete with both the X and the Y chromosome present. An error occurring in paternal meiosis II, when X and Y are already separated, can only produce gametes with XX or YY chromosomes that, in combination with a normal oocyte, would result in a XXX or XYY karyotype. The evidence behind errors in paternal meiosis is not as clear, with some studies suggesting that older fathers have a higher tendency to produce XY sperm, while others have shown no affect of age on XY recombination. Because the female oocyte carries only X chromosomes, errors occurring either in meiosis I or II can produce gametes with 2 X chromosomes and hence a zygote with XXY karyotype. Most maternal errors occur in meiosis I. An association of aneuploidy with advanced maternal age has been reported, although it has only been seen with errors occurring during meiosis I; meiosis II errors do not

seem to be more common with increasing maternal age. A postzygotic mitotic error can also contribute to the Klinefelter phenotype in a small number of cases. Some patients have been found to have a mosaic karyotype, including cells with XY and XXY. The degree of mosaicism varies between patients and even between different tissue samples of the same patient. Individuals with XXY/XY mosaicism tend to have a better prognosis for testicular function.

Klinefelter syndrome has phenotypic variability because of the X chromosome inactivation that normally takes place in all human cells that contain more than 1 X chromosome. All but 1 X chromosome undergo inactivation per Lyon hypothesis (with the formation of an equal number of Barr bodies) and this is the mechanism by which overexpression of genes located on the X chromosome is prevented. In the case of Klinefelter syndrome, as in several other genetic conditions, the process of inactivation does not occur randomly, but a specific X chromosome, either paternal or maternal, tends to be inactivated more frequently. This is a process known as preferential or skewed X chromosome inactivation and has important clinical implications. The androgen receptor gene AR, by which testosterone exerts its action, is located on the X chromosome and contains a trinucleotide (CAG) repeat sequence. Every X chromosome contains a different number of CAG repeats in the AR gene, and shorter numbers of repeats have been associated with better response to androgen therapy and higher level of education compared to longer repeats. Most patients with Klinefelter syndrome have been shown to have the X chromosome with the shorter CAG repeat number preferentially inactivated; thus, the allele with the longer CAG repeats is active in most cells and is thought to be the cause of hypogonadism in most patients with Klinefelter syndrome.

Klinefelter syndrome results in a form of primary testicular failure, decreased testosterone production, and thus elevated levels of gonadotrophin luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Testicular function can be markedly decreased from fetal life, although in most patients it remains at normal levels until puberty when a significant increase in gonadotrophin levels is noted with a concomitant decrease of testosterone production in the lower levels of normal.

## DIAGNOSIS

The diagnosis of Klinefelter syndrome at birth is difficult to make, because most patients do not have specific phenotypic characteristics or distinct facial dysmorphic features. Some 47,XXY male newborns and infants will present for evaluation of cryptorchidism or small phallus. Up to 26% of newborns and infants were found to have minor dysmorphic features, such as clinodactyly, in a recent study, while 18% had major malformations. As toddlers, patients will usually present with developmental delay involving expressive language. At school age, most affected individuals will require assistance with reading and spelling. In addition to learning difficulties, some children might have behavioral and social problems. At an older age or during puberty, patients might seek evaluation for incomplete pubertal development, gynecomastia, and small testes.

In adulthood, infertility and breast cancer are common reasons for referral of patients with Klinefelter syndrome.

Klinefelter syndrome can be diagnosed prenatally based on the chromosome analysis of amniocytes obtained through amniocentesis (14–16 weeks) or chorionic villi from a chorionic villus sampling (11–12 weeks) in pregnancy. Diagnosis is also possible with noninvasive prenatal testing using cell-free DNA in the maternal blood (screening test). If the diagnosis is not made in the prenatal period, chromosome analysis from peripheral blood lymphocytes can be performed based on findings of the clinical examination. Barr-body analysis is a quick alternative for diagnosis, with sensitivity as high as 82%, although it is not widely used today. Additionally, androgen receptor gene quantitative real-time PCR (AR-qPCR) technique is a screening technique that detects the number of AR genes present and thus the number of X chromosomes.

## SIGNS AND SYMPTOMS

### Physical Examination

Individuals with Klinefelter syndrome tend to have longer arms and legs, with a low upper-to-lower segment ratio. Biacromial diameter is also low, probably secondary to low testosterone levels. Height ranges from the 25th to the 99th percentile for age, while mean height is at the 75th percentile. Most of the gain in height takes place between the ages of 5 and 8 years. Head circumference and weight are usually at the 50th percentile.

During childhood, testicular volume and penile length are slightly lower than normal. Later in development during adolescence, testicular size remains small, with a length usually less than 2.5 cm and average volume of less than 4 mL. Many individuals will enter puberty normally, but testosterone levels tend to decrease in late adolescence to adulthood. With an insufficient amount of androgens present, usually less than half the level seen in unaffected individuals, secondary sexual characteristics do not completely develop and virilization is inadequate. Sparse body and facial hair is present, along with gynecomastia in more than half of adolescent patients. Most patients are infertile, with hyalinization and fibrosis of the seminiferous tubules by mid-puberty. Although only a minority of individuals with Klinefelter syndrome have viable sperm in the ejaculate, and thus are able to provide sperm for cryopreservation, recent advances in reproductive technology including testicular sperm extraction (TESE) and intracytoplasmic sperm injection (ICSI) have significantly increased their reproductive potential.

Fifth finger clinodactyly is the most common minor anomaly and is present in almost one-third of patients. Cleft palate, cryptorchidism, and inguinal hernia are other major anomalies. Other abnormalities reported are mitral valve prolapse, scoliosis, increased frequency of chronic bronchitis and diabetes mellitus, severe acne, and hypospadias.

### Psychological Performance

The intelligence quotient (IQ) scores for Klinefelter syndrome patients vary widely, from well below to well above average. The mean IQ score is reported to be

between 85 and 90. The number of extra X chromosomes adversely affects the final intellectual performance, and it is thought that each extra chromosome decreases the IQ score by 15 to 16 points. The verbal IQ score is usually lower than the performance IQ score, most likely secondary to auditory processing and expressive language difficulties. Auditory memory is also affected, causing reading and spelling problems. Expressive language is more severely affected than receptive skills and comprehension. Individuals with 47,XXY karyotype tend to present with a variety of behavioral issues—more commonly shyness, immaturity and social insecurity. Problems in the formation of peer relationships also occur, while 1 study reported increased anxiety and substance abuse among adolescents with Klinefelter syndrome. Significant psychiatric problems are not commonly encountered.

## DIFFERENTIAL DIAGNOSIS

Since the clinical presentation of Klinefelter syndrome can vary, a high index of clinical suspicion is necessary to reach a diagnosis in most patients. More specifically, the diagnosis should be suspected and karyotype testing should be considered in the presence of the following:

- Small testicular size
- Long upper and lower extremities
- Infertility
- Developmental delay
- Behavioral problems
- Hypogonadism (weakness, fatigue, gynecomastia, decreased libido, erectile dysfunction)

Other causes of hypogonadism, such as Kallmann syndrome, should be considered. The physician should also consider and exclude other causes of infertility in males. The tall stature and lean physical features of the syndrome should prompt for evaluation of potential signs of Marfan syndrome. In addition, speech delay and low IQ scores in a male patient can be seen with Fragile X syndrome, for which simple genetic testing is available. Finally, males with SRY gene translocations to the X chromosome have a 46,XX karyotype and can present with several of the characteristic findings of Klinefelter syndrome, such as hypogonadism, azoospermia, gynecomastia, and hyalinization of the seminiferous tubules.

## LABORATORY FINDINGS

Karyotype analysis as a gold standard will reveal 2 or more X chromosomes in addition to a Y chromosome in a phenotypical male. Chromosomal microarray analysis would also detect Klinefelter syndrome, because it represents duplication of X-chromosomal material. FSH, LH, and estradiol levels are elevated. Testosterone levels when not on testosterone therapy are in a low to low-normal range. Inhibin B decreases to undetectable levels after puberty. A complete hormonal evaluation includes FSH, LH, testosterone, estradiol, insulin-like growth factor (IGF)-1, and prolactin levels. Cortisol levels should be measured because of the increased frequency of adrenal steroidogenic deficiency in patients with Klinefelter syndrome.

The decreased bone formation and increased bone resorption resulting in osteopenia are manifested by

decreased serum osteocalcin levels and increased hydroxylproline-to-creatinine ratio. Routine bone density screening is recommended to test for osteopenia or osteoporosis.

Although individuals with Klinefelter syndrome are at increased risk of deep venous thrombosis and pulmonary embolism, it is not clear whether routine testing for thrombophilia in all patients with the syndrome is indicated.

## HISTOLOGY

Histologic findings from testicular biopsies of prepubertal patients reveal reduced numbers of germ cells with normal numbers of Sertoli and Leydig cells. Later in adulthood, hyalinization of seminiferous tubules with fibrosis and rare, if any, foci of spermatogenesis are seen. Gynecomastic breasts reveal hyperplasia of interductal tissue.

## IMAGING

Mitral valve prolapse can be diagnosed with the use of echocardiography. Diagnostic radiography is performed to evaluate for radioulnar synostosis and taurodontism (vertical enlargement of the body of the tooth affecting molar teeth) that are occasionally seen in this disorder.

## MANAGEMENT

The treatment of patients with Klinefelter syndrome should be based on a multidisciplinary approach by different specialists, including pediatricians, geneticists, endocrinologists, infertility specialists, and speech therapists. Support from a clinical psychologist or psychiatrist is often necessary.

Management strategies depend on the age at diagnosis, and speech delay should be carefully addressed by a speech therapist in early childhood because it is among the most common presenting symptoms and can affect future performance at school. Other learning disabilities are also common, and monitoring of school performance with appropriate specialist referrals as needed is necessary.

Males with 47,XXY presenting with motor skills delay can be hypotonic, with balance and coordination impairment. Also, fine motor skills are affected and dyspraxia can be prominent. These patients can benefit from expert assessment by physical and occupational therapists.

Treatment with testosterone should be started as early as possible, and certainly by the onset of puberty when gonadotrophin levels begin to increase. Although testosterone supplementation will not treat infertility, gynecomastia, and small testicular size, it is considered necessary for an increase in muscle bulk and bone mineral density. Other benefits of testosterone treatment are proper development of secondary sexual characteristics along with increases in energy and concentration ability. It has also been shown that, when on testosterone treatment, patients tend to have fewer problems with social interactions. Treatment should be continued for life to reduce the occurrence of osteoporosis, autoimmune disease, diabetes mellitus, and obesity.

It is suggested that treatment begin at around the age of 12 years, at the beginning of puberty, even if the levels of testosterone are in the low-normal range.

Careful adjustment of the dose can lead to normalization of serum concentrations of testosterone, estradiol, FSH, and LH. All patients with increased gonadotrophin levels should be treated, as well as those with symptoms of hypogonadism, such as decreased libido and fatigue. The aim is to achieve a testosterone level in the middle of the normal range. Testosterone treatment can cause weight gain secondary to increased lean body mass and fluid accumulation. Acne, low HDL cholesterol levels, and erythrocytosis are other potential complications.

Patients diagnosed with micropenis can be treated with topical testosterone in the form of a cream or testosterone injections with encouraging results. Gynecomastia can be treated with mastectomy.

### Fertility-Reproductive Options

Testosterone replacement therapy does not have any positive effect on fertility, and it is suggested that it might negatively affect future fertility treatments with techniques such as ICSI and TESE. Testosterone can block spermatogenesis at the stage of spermatogonial differentiation.

Individuals with Klinefelter syndrome have significantly decreased fertility rates, and spontaneous paternity has only been reported in anecdotal cases. Recent techniques of recovery of spermatozoa from the testes of patients with the use of TESE and ICSI have dramatically changed the fertility outcomes. Livebirth rate was reported to be as high as 20% in 1 study. Because patients with 47,XXY have a progressive-germ cell depletion even before infertility occurs, the option of cryopreservation of sperm for the future should be offered. Most of the offspring born to patients with Klinefelter syndrome have a normal karyotype, which is anticipated because most spermatozoa obtained with TESE and implanted through ICSI are normal. Nevertheless, the frequency of hyperploid spermatozoa produced by Klinefelter patients is increased compared to unaffected individuals, and a higher risk of offspring with Klinefelter syndrome should be explained during counselling.

## GENETIC COUNSELING

Karyotypic analysis is not routinely performed in parents of patients with Klinefelter syndrome. The recurrence risk is thought to be less than 1%. There is an increased risk of aneuploidy and a higher frequency of trisomy 21 in the offspring. Preimplantation genetic diagnosis and prenatal diagnosis should be offered.

## COMPLICATIONS

### Breast Carcinoma and Other Tumors

The risk for breast carcinoma in patients with 47,XXY is several times higher than that of karyotypically normal males of the same age. Although a Danish study with cancer registry data did not show an increased incidence of breast cancer in those patients, the risk in other studies has been reported to be 20 to 50 times higher. This has been attributed to the increased concentration of estradiol in men with Klinefelter syndrome, secondary to peripheral conversion of testosterone to estradiol. Nevertheless, the risk seems to

be less than that of normal females. Increased surveillance for breast cancer during routine annual physical examination seems reasonable given the above data, even though more studies are necessary to assess the cost-benefit ratio of such an approach. The Danish registry that could not confirm the increased risk of breast cancer did show an association with mediastinal germ-cell tumors. Also, mortality from lung cancer and incidence of non-Hodgkin lymphoma seem to be elevated.

### Autoimmune Diseases

The risk of autoimmune diseases, including rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome, is increased and considered to be similar to that seen in females.

### Endocrine Complications

Patients with Klinefelter syndrome are at increased risk of developing diabetes mellitus, as shown by recent epidemiologic data. They tend to have increased levels of LDL cholesterol and decreased levels of HDL cholesterol compared to controls, while most of them fulfill criteria for the diagnosis of metabolic syndrome. In concordance with these findings, fasting plasma insulin levels and insulin resistance are higher in Klinefelter patients compared to controls.

Hypothyroidism and hypoparathyroidism are also known to occur more frequently.

### Varicosities

Venous stasis can result in the development of varicose veins and venous ulcers. The prevalence of venous leg ulcers is 20 to 50 times higher than the general population.

### Osteoporosis

Hypogonadism is known to be a cause of secondary osteoporosis, and multiple studies have shown decreased bone mineral density in patients with Klinefelter syndrome compared to controls. Between 25% and 40% of the patients will have decreased bone density of various severity, which can progress to osteoporosis. It seems that there is an increased morbidity and mortality from this complication since epidemiologic studies have shown increased rates of admission to the hospital for hip, forearm, and spine fractures, and an increased risk of death from hip fractures.

### Cardiovascular Disease

Two studies have demonstrated increased mortality from cardiovascular disease in patients with Klinefelter syndrome. This is not attributed to the mortality risk from ischemic heart disease, which is actually lower in those patients, but to the higher incidence of mitral valve prolapse and hypostatic leg ulcers. Mitral valve prolapse is related to increased risk of sudden death, and leg ulcers have been associated with increased risk of deep venous thrombosis and pulmonary embolism.

## PROGNOSIS

The overall prognosis of Klinefelter syndrome is considered to be good, although the final prognosis depends on the occurrence of complications. Males

with 47,XXY karyotype may have difficulties through adolescence and they may encounter academic difficulties as well as behavioral issues. Most of them will become independent from their families in later life and achieve normal functional levels. Life span is also considered to be normal.

## Chapter 282

# LABIAL ADHESIONS

Linda S. Nield, MD

Labial adhesions, also known as labial agglutination or synechia vulvae, are membranous structures that develop as a result of fusion of the adjacent mucosal surfaces of the labia minora. The membranous structure can vary from thin and transparent to thick and fibrous. Any degree of labial involvement can occur, including covering of the urethral meatus. The condition is self-limited, and spontaneous resolution in affected individuals has been reported to occur in 50% of cases within 6 months, 90% of cases within 12 months, and 100% of cases within 18 months.

## ETIOLOGY

The exact cause of labial adhesions is uncertain, but the condition is likely caused by chronic irritation and inflammation of the hypoestrogenic vulva. Physical or chemical trauma, infection (*Candida albicans*, *Enterobius vermicularis*, and various bacteria), and poor hygiene are the triggers for the chronic inflammation. Sexual abuse may also be a source of chronic irritation, but labial adhesions are generally considered a nonspecific finding. During healing of the irritated area, the medial edges of the labia minora adhere to each other, forming an adhesion.

## EPIDEMIOLOGIC MECHANISM

Prepubertal girls in the first 5 years of life are most prone to this condition. A rise in endogenous estrogen levels during the prepubertal period may be the reason for a decrease in the occurrence of labial adhesions in older preadolescent girls. Improved hygiene may also be a factor. Reported incidences of labial adhesions in preadolescent girls in the general pediatric setting range from approximately 2% of girls who are identified by inspection alone to 39% of girls identified with inspection plus magnified photographic images of the vulva. Labial adhesions were found in 15.6% of girls who were referred to a gynecology clinic for various hymenal findings that were documented during well-child evaluations. Labial adhesions in a neonate are a rare occurrence, presumably because of the protective influence of maternal estrogen. Healthy, postpubescent young women do not develop labial adhesions, but they have been described after episiotomy, herpes infection, trauma, treatment with chemotherapy, and graft-versus-host disease.

## DIFFERENTIAL DIAGNOSIS

Ambiguous genitalia, vaginal agenesis, imperforate hymen, or septated hymen may be confused with labial adhesions, but physical examination easily differentiates these entities from one another. A line of demarcation between the clitoral hood and labia minora is seen with labial adhesions (Figure 282-1), but not with ambiguous genitalia secondary to androgen

**Figure 282-1** A commonly found presentation of labial adhesion in a 3-year-old.

excess. In vaginal agenesis and hymenal variants, the labia are normal and unfused, and the characteristic findings of these entities are located within the vaginal introitus.

### CLINICAL MANIFESTATIONS

Labial adhesions are often asymptomatic and are typically discovered at routine well-child visits or brought to the attention of the pediatrician by the child's caregiver. However, the adhesions can partially dehisce, leading to spotting of a minute amount of blood as well as irritation. Uncommonly, affected girls may complain of vaginal pain or of pain with ambulation or urination, or may suffer from a urinary tract infection, urinary retention, or an altered urinary stream.

The condition is diagnosed by visual inspection of the vulva, which includes a hymenal examination in the supine frog-leg or prone knee-chest position. The labia majora should be gently stretched apart, and a membrane of variable length and thickness is seen in the midline. A small opening near the clitoris allows the outflow of urine. A line of adhesion between the 2 nonrugated labia minora or raphae can also be seen.

### MANAGEMENT

#### Uncomplicated Case

If the child has no accompanying symptoms, then labial adhesions should not be treated. The parents should be informed of the diagnosis, and an opportunity to visualize the adhesion should be provided so that the parents are not surprised and concerned about the unusual appearance of the vulva. Reassurance of the benign, self-limited nature of this condition and education about potential symptoms should be provided.

#### Complicated Case

If the child has accompanying symptoms such as pain on urination or ambulation, altered urinary stream, urinary retention, or a history of urinary tract infections, then a urinalysis and urine culture should be obtained. Any documented urinary tract or vulvar infection should be treated accordingly. The first-line treatment of the complicated labial adhesion is the

application of topical estrogen. Retrospective reviews of girls treated with topical betamethasone have revealed its similar efficacy to topical estrogen. A cream containing 0.625 mg/gm of conjugated estrogen (Premarin Vaginal Cream, Wyeth Ayerst) can be applied to the adhesion and labial edges with a finger tip or cotton swab. Gentle traction can be placed on the opposing labia during the application of the estrogen cream. Although the optimal dosing and length of treatment are unknown, a course of twice-daily application for 2 weeks is a reasonable starting point. The goal is to use the least amount of medication that will achieve separation of the adhesion. Topical estrogen should be applied for 10 to 14 days with a cotton-tipped applicator with light pressure over the adhesion; this treatment is highly effective for most thin, transparent adhesions, but less so in others that are dense and fibrous or longstanding. Even the dense adhesions should be treated initially with topical estrogen because this treatment produces thinning of the line of fusion that facilitates manual labial separation in the office. The possible adverse effects of the topical estrogen include local irritation, breast budding, breast tenderness, and vulvar hyperpigmentation, all of which are reversible with discontinuation of the medication. After the estrogen therapy has separated the labia, a topical lubricant (eg, white petroleum jelly) should be applied to the affected area for several months on a daily basis to ensure complete healing and persistent separation of the opposing labial edges.

Treatment with estrogen cream is considered unsuccessful if labial separation has not occurred within 8 weeks or if the child suffers untoward effects from the estrogen and cannot continue using it. If topical estrogen is unsuccessful and the girl's accompanying symptoms persist, then manual separation of adhesions can be performed. Before manual separation is performed, topical anesthetic must be applied to the affected area. After the anesthetic has taken effect, firm traction on the opposing edges of the labial minora is applied to separate the fused edges. The edges should be smoothly peeled away from each other. After separation, a lubricant should be applied to the affected area on a daily basis for several months to prevent readherence. Warm soaks or sitz baths in the days following separation may provide relief if the vulva is irritated from the procedure.

Rarely, in cases of thick labial adhesions that cannot be separated by the previously described treatments and those that are associated with complications, surgical lysis by a pediatric urologist or gynecologist while under general anesthesia may be required (Figure 282-2). Postoperative care includes sitz baths in the immediate postoperative period and several months of application of topical lubricant. The decision to treat labial adhesions with surgery is made by weighing the significance and severity of symptoms after less aggressive treatments have failed versus the risks of general anesthesia.

### PREVENTION: ADVICE TO PARENTS

The physician should explain the value of proper hygiene of the vulva and educate the parents about practices to help their child avoid recurrent labial which

**Figure 282-2** Extensive labial adhesion in a 4-year-old. Hydronephrosis is a potential rare complication of an extensive labial adhesion.

include: (1) wiping front to back after urination or defecation, (2) wearing cotton underwear, (3) avoiding the application of detergents in the genital area, and (4) avoiding wet, tight clothing against the vulva for prolonged periods.

#### WHEN TO REFER

A symptomatic child with persistent or recurrent labial adhesions who has a history of urinary tract infections or complaints of urinary retention, altered urinary stream, dysuria, or pain with ambulation and has failed topical estrogen therapy should be referred to a pediatric urologist or gynecologist for surgical lysis.

## Chapter 283 LEAD POISONING

Michael Weitzman, MD

The near eradication of acute lead encephalopathy represents one of the great pediatric public health success stories in the United States. Virtually no children in the United States die from this disease any longer,

and most pediatricians today have never seen a child who has overt symptoms resulting from this condition. Despite this success, however, a large number of children continue to be identified with levels of lead exposure that affect their health, and severe toxicity and even deaths still occur, as evidenced by reports of accidental ingestion of lead-containing necklaces and metallic charms. More commonly, children often are exposed at low levels previously thought to be harmless but that are now recognized to impair cognition and behavior. Thus, continued efforts in the areas of primary prevention, screening, public education, and removal of sources of lead are needed.

### EPIDEMIOLOGIC FEATURES OF CHILDHOOD LEAD POISONING

Blood lead levels of children in the United States have declined dramatically, as measured by the National Health and Nutrition Examination Surveys. The geometric mean blood lead level of children 1 to 5 years of age has declined from 15 mcg/dL in the 1976 to 1980 survey, to 2.7 mcg/dL in 1991 to 1994, and most recently to 1.34 mcg/dL in 2007–2010. These changes have been accompanied by corresponding declines in the prevalence of 1- to 5-year-old children with elevated blood levels ( $\geq 10$  mcg/dL), from 77.8% (1976–1980), to 4.4% (1991–1994), to 1.6% (1999–2004) to 0.8% (2007–2010). Racial differences in mean blood lead levels and rates of elevated blood lead levels have also diminished, as has the difference between the rates of elevated blood lead levels in those covered by Medicaid and those not covered by Medicaid, although black children and children covered by Medicaid continue to have higher rates than white children and those not covered by Medicaid. At the same time that these declines occurred, a consistent and widely accepted research literature has emerged demonstrating adverse neurodevelopmental and behavioral consequences of lead exposure in children at levels previously believed to be safe. In fact, the Centers for Disease Control and Prevention (CDC) has recently stated that it is now clear that there is no known threshold below which adverse effects of lead are absent.

### SOURCES OF LEAD

For most children, lead-contaminated interior and exterior household paint that has chipped, peeled, or chalked in their primary residence or in the homes of relatives, babysitters, or child care providers remains the most common and the most concentrated source of exposure. Most often, lead-contaminated dust, rather than actual paint chips, is the source of the exposure. As detailed in a survey report by the US Department of Housing and Urban Development, the older the house, the more likely it is to contain lead-based paint; the less affluent the family, the more likely this paint is to be in disrepair. Housing built before 1950 poses the greatest danger of exposure, although lead-based paint was not completely banned until the late 1970s. Nationwide, the number of pre-1950 housing units decreased from 29.2 million in 2001 to 28.2 in 2009, indicating a decline in such

housing because of aging of our housing stock and consequent demolition.

Numerous other sources of lead exposure exist. Children may be exposed to lead in water, food, soil, toys, or ceramics. Parents whose clothing becomes contaminated with lead at work may inadvertently bring lead into the home. Occupations at high risk for take-home exposures include those involving battery production or recycling, the making of pottery, smelting, printing, paint contracting, and working on a firing range, in a brass foundry, or on the demolition or renovation of outdoor structures. In addition, a significant number of hobbies can place children at risk, such as making lead fishing sinkers or bullets, collecting lead figurines, spending time at indoor firing ranges, and making ceramic pottery.

In certain cultures, such as many Latin American and Southeast Asian cultures, some home remedies, such as azarcon and greta, can serve as sources of lead poisoning. Certain cosmetics, such as kohl, an eye makeup from the Middle East and South Asia, can contain more than 80% lead. Lead-glazed ceramic dishes and containers also can cause lead poisoning, especially if acidic foods such as salad dressings or citric acid juices are served on or stored in them. These sources should be considered when children who are recent immigrants are poisoned. Lead plumbing also remains an important source, especially in areas with older water supplies. This contamination was evidenced in 2003 to 2004 by the elevated lead concentrations found in Washington, DC, after changes in water disinfection procedures caused leaching of lead out of water service pipes. In addition, maternal lead stores can be transferred to infants prenatally and in breast milk, thereby contributing to an infant's lead exposure. Although not advocating universal screening of pregnant and lactating women, the CDC has offered guidance to state and local health departments in identifying populations at increased risk for lead exposure and identifying community-specific risk factors to guide physicians in determining the need for population-based blood lead testing of these women.

### ADVERSE HEALTH EFFECTS

Exposure to lead has numerous adverse health consequences. Most pediatricians' concerns, however, focus on the adverse neurocognitive effects of lead toxicity. Adverse neurocognitive effects caused by blood lead levels above 10 mcg/dL have been recognized for some time. Over the past decade, it has become increasingly recognized that lead levels well below 10 mcg/dL cause similar negative outcomes. A pooled analysis of findings from 7 prospective studies involving 1,333 children has shown lowered IQ scores that are independently associated with the lowest measurable levels of blood lead: as blood lead levels increase from 2.4 to 10 mcg/dL, there is a 3.9 IQ point decrease; between 10 and 20 mcg/dL, there is an additional 1.9 IQ point decrease; and between 20 and 30 mcg/dL, there is an additional 1.1 IQ point decrease. At this time, it is not possible to ascertain whether a child's peak blood lead level, the average over the child's early years, or a blood lead level taken

in proximity, time-wise, to a child's standardized IQ test is most predictive of the magnitude of IQ decrease. An impressive array of studies now show IQ losses and increased rates of adverse outcomes for a substantial number of other aspects of children's functioning, including attention, vigilance, language development, the transfer of information from short-term to long-term memory, aggression, and antisocial or delinquent behaviors associated with blood lead levels as low as 5 mcg/dL. These findings clearly indicate that blood lead levels well below 10 mcg/dL are associated with subtle but potentially serious alterations of children's neurocognitive functioning. No apparent threshold exists for the toxic effects of lead; that is, negative cognitive effects occur at the lowest measurable levels of blood lead. As a consequence, The CDC now defines a blood lead level that is at the 97.5th percentile, which currently is 5 mcg/dL, as being elevated. Prenatal lead exposure has also been studied and has been negatively associated with intellectual development of school-aged children.

### SCREENING FOR ELEVATED BLOOD LEAD LEVELS

Primary prevention has certainly proved the most effective means of eliminating lead poisoning in the United States, and even more intensive large-scale primary preventive measures, such as more aggressive housing rehabilitation, have been advocated. However, to identify children who need individual interventions to reduce their blood lead levels, screening of blood samples remains an essential tool in the prevention of childhood lead poisoning. Guidance from the CDC has been pivotal in defining national standards for screening programs. The CDC recommends the use of venous or capillary blood lead level as the laboratory examination of choice.

Although capillary blood samples collected by finger stick are acceptable, the potential for contamination by lead deposits on the skin dictates that capillary specimens with values at or above 5 mcg/dL be confirmed with a venous sample. An important point to recognize is that the allowable error established by the Clinical Laboratory Improvement Amendments for lead testing is  $\pm 4$  mcg/dL or 10% of value, whichever is greater. At low levels of blood lead, allowable laboratory error can result in misclassification that might affect management recommendations for an individual child.

CDC guidelines advise state health officials to develop universal or targeted screening programs (or both) based on the risk characteristics of their local communities. Within the state or the locale for which recommendations are made, the CDC advises that child health care professionals use blood lead tests to screen 1- and 2-year-olds (and 3- to 6-year-olds who have not been screened previously) who meet one or more of the criteria in Box 283-1.

Screening by questionnaire to evaluate risk has been suggested by the CDC, but substantial variability in the sensitivity and specificity of screening questionnaires limits the usefulness of this screening strategy. Screening questions are still used by some states and localities as one component of an overall lead-screening strategy,

### BOX 283-1 Recommendations for Lead Screening in Children at Risk

Universal screening of all children on Medicaid between 9 and 12 months and at 2 years of age has been required, but with decreases in the rates of elevated blood lead levels between those covered by Medicaid and those not covered by Medicaid, the CDC has recommended that state and local officials have the flexibility to develop blood lead screening strategies that reflect local risks for elevated blood lead levels. In addition, or until local health officials provide data-based guidelines for screening, the following guidelines are useful for deciding whether a child should be screened:

1. A child whose parents are concerned that the child may have been exposed
2. A child who lives in or regularly visits a house with peeling or chipping paint built before 1980
3. A child who lives in or regularly visits a house with recent or ongoing renovation or remodeling
4. A child who has a sibling or a playmate with an elevated blood lead level
5. A child who lives with an adult whose job or hobby involves exposure to lead
6. A child who lives near an active lead smelter, battery recycling plant, or other industry likely to release lead
7. A child who is a recent immigrant, refugee, or foreign adoptee
8. A child who has a household member who uses traditional, folk, or ethnic remedies or cosmetics or who routinely eats food imported informally (eg, by a family member) from abroad
9. A child who has recently immigrated to the United States or who has been internationally adopted

From Centers for Disease Control and Prevention. Recommendations for blood lead screening of Medicaid-eligible children aged 1-5 years: an updated approach to targeting a group at high risk. *MMWR Morb Mortal Wkly Rep.* 2009;58(RR09):1-11.

often with modifications in the specific questions used based on the locale. State- and locale-specific screening strategies are available on the CDC Web site at [www.cdc.gov/HealthyHomes/programs.html](http://www.cdc.gov/HealthyHomes/programs.html). The Web site [www.aoc.org/pehsu.htm](http://www.aoc.org/pehsu.htm) lists regional pediatric environmental health specialty programs that may be extremely useful to physicians caring for children.

In addition to following state- or local-level guidelines, health care professionals are encouraged to go beyond these recommendations by remaining vigilant in identifying children who should be screened because of exposure to less common sources of lead, such as those resulting from various parental occupations or hobbies. Similarly, if parents or health care professionals suspect lead exposure, prompt performance of a blood lead test should be undertaken, regardless of patient age, general health department recommendations, or responses to screening questionnaires.

Of course, to be optimally effective, a screening policy is not enough; physicians must participate in and comply with the recommended program. Also,

effective treatment of children with elevated blood lead levels requires that primary care physicians collaborate with local health, public housing, and social services to help identify sources of a child's exposure and ways to eliminate them or to provide the children with alternative housing when necessary.

*Healthy People 2010* called for the elimination by the year 2010 of all lead levels over 10 mcg/dL in children. Although most physicians agree that lead exposure remains a major problem, concern is growing about the cost benefit of using blood lead level as a screening tool in an era of declining prevalence. This concern is addressed in a 2005 policy statement from the American Academy of Pediatrics, which reviews a cost-benefit analysis of lead screening. Although the cost of lead screening is not trivial, the projected loss of income among individuals who suffered IQ decrements caused by lead exposure in childhood is in the hundreds of billions of dollars.

### Follow-Up of Positive Screening Tests

The CDC has recommended a schedule of follow-up testing based on the initial screening result (Table 283-1).

#### Children with blood lead values above 5 mcg/dL

All children with blood lead levels at or above 5 mcg/dL are encouraged to have ongoing monitoring for continuing lead exposure. If the elevated blood lead level was obtained by a finger-stick blood test, it should be confirmed with a venous blood lead test. All children with venous blood lead levels of 5 mcg/dL or higher are recommended by the CDC to receive both medical and environmental evaluations and medical and environmental counseling.

The evaluation consists of (1) a detailed medical, nutritional, developmental, and environmental history, and a complete physical examination; (2) a laboratory evaluation of iron status, including hematocrit and mean corpuscular volume; those with a low hematocrit or low mean corpuscular volume should be tested either with a ferritin level or iron and iron-binding capacity levels to identify iron deficiency; and (3) an environmental history to identify potential sources of the child's exposure, such as living in or visiting a home built before 1950, or one built between 1950 and 1978, when lead-based paint was still being used in some homes. The physical examination is unlikely to reveal overt signs of neurological damage, but this in no way precludes the possibility that the child has sustained neuropsychological injury that may manifest as attention-deficit/hyperactivity disorder or specific learning disabilities.

Such children should receive a nutritional assessment to identify eating patterns that may result in increased absorption of lead from the gastrointestinal tract, such as iron deficiency, low calcium intake, or infrequent meals. Many children with blood lead levels of 5 mcg/dL or higher are eligible for support from the Special Supplemental Nutrition Program for Women, Infants and Children and should be referred for evaluation of eligibility. Iron deficiency, even in the absence of anemia, should be treated with iron supplements, because iron deficiency increases the amount of

**Table 283-1** Recommended Schedule for Obtaining a Confirmatory Venous Sample

SCREENING TEST RESULT (mcg/dL)	RECOMMENDATION FOR CONFIRMATION TESTING
5–<10	Confirm with a venous lead level, within 1–3 months if possible; this should be ongoing until the level is <5 mcg/dL
10–44	Confirm the blood lead level with a venous sample within 1–3 months for those children with a blood lead level of 10–24 mcg/dL and within 2 weeks–1 month for those children with a blood lead level of 25–44 mcg/dL. Repeat confirmations at the same intervals until blood lead levels decline (ie, for children with repeat blood lead levels of 25–44 mcg/dL, repeat the blood lead test at 2 weeks–1 month intervals until it is in the range of 5–24 mcg/dL, at which time blood lead testing should be repeated at 1–3 month intervals until it is below 5 mcg/dL.

The higher the blood lead level on the screening test, the more urgent will be the need for confirmatory testing. Adapted from Centers for Disease Control and Prevention. *Screening Young Children for Lead Poisoning: Guidance for State and Local Public Health Officials*. Atlanta, GA: US Department of Health and Human Services; 1997.

ingested lead that is absorbed from the gastrointestinal tract and has also been found to be independently associated with increased rates of neurobehavioral problems. Although the protective effect has not been proved, increased calcium intake is generally recommended, especially when calcium intake is low. Increasing meal frequency may decrease lead absorption, but this action should be prescribed in the context of a diet that is not excessive in calorie content. All such children should receive general nutritional counseling consistent with American Academy of Pediatrics guidelines.

As elevated lead levels increase the risk for decreased IQ and subtle or overt neurocognitive and behavioral problems, monitoring these aspects of child function is particularly important, and referral for formal developmental, neuropsychological, or educational psychology evaluations are indicated if there is any concern about the child’s development, educational performance, or behavior, such as inattention or hyperactivity. The potential need for early intervention or special educational services for children evidencing possible difficulties in these areas should be an important consideration in the management of children with blood lead levels at or above 5 mcg/dL.

Families need education about potential sources of lead exposure, means to reduce exposure (Box 283-2), and housing and public health regulations concerning lead that may assist them in reducing their children’s lead exposure. A detailed history to help identify potential sources of lead exposure is indicated. In many communities children with elevated blood lead levels of varying degrees (eg, 15, 10 or even 5 mcg/dL) will become involved with local health departments that may do home inspections to identify lead paint hazards, household dust that has elevated amounts of lead, or other potential sources of exposure, and facilitate recommended or mandated abatement of lead-based household paint. Although often a lengthy process, abatement of lead-based hazards and subsequent dust control are cornerstones of treatment for children with exposure to lead resulting in elevated blood lead levels.

Thus it is obvious that children with elevated blood lead levels often benefit from case management

involving professionals from multiple fields, and a medical home is essential to their care, with pediatricians involved in all aspects of their lead-related care.

Families should be counseled to (1) have lead-based paint abatement performed by a properly licensed contractor and, if possible, with supervision of the local health department; (2) relocate children and pregnant women to another site while abatement is being performed; and (3) have a thorough cleanup of dust before allowing children to reinhabit the home.

The use of chelating agents for children whose blood lead levels are less than 45 mcg/dL is not indicated. A prospective study randomized 2-year-old children with lead levels between 25 and 44 mcg/dL to receive succimer (dimercaptosuccinic acid) or placebo, with up to 3 treatment courses of 26 days each, over 6 months. The authors found no appreciable difference in lead levels and no significant differences in measures of cognition or behavior between the succimer-treated and placebo groups at follow-up at age 7 years. The effects of succimer when used in more prolonged or more repeated treatment courses would require further study.

The CDC recommends that any blood lead value that is at or above the reference value of 5 mcg/dL and less than 10 mcg/dL should be confirmed within 1 to 3 months, and this should be ongoing until the level comes down to below 5 mcg/dL. Blood lead values of 10 to mcg/dL and higher should be confirmed as follows:

- 10 to 24 mcg/dL: confirm within 1 to 3 months
- 25 to 44 mcg/dL: confirm within 2 weeks to 1 month
- 45 to 69 mcg/dL: confirm within 48 hours

Patients with blood lead values of 70 mcg/dL or higher: should be treated emergently and have their blood lead levels retested immediately.

**Children with blood lead values of 45 mcg/dL or higher**

The clearest management strategies exist for children in this category because they are at the greatest risk for overt lead encephalopathy. Broad consensus exists that such children must be removed from sources of lead in their environments and receive chelation therapy, as described in Chapter 369, Poisoning. Any

### BOX 283-2 Avoiding Lead Hazards in the Home

Cover leaded paint that is chipping or peeling.  
 Move cribs, playpens, furniture, and play areas away from chipping or peeling paint.  
 Wet-mop floors and wet-clean windowsills and window wells with a high-phosphate detergent.  
 Avoid dry dusting or sweeping.  
 Wash children's hands, toys, and pacifiers regularly.  
 Use cold water for cooking; run tap water for 2 to 3 minutes every morning before using.  
 Repair deteriorated windowpanes inside the house and on porches.  
 Replace old windows.  
 Remove paint in old homes (only by trained contractors). Families must be out of their homes during paint removal.  
 Postabatement cleanup, preferably by professional house cleaners, is essential, and the measurement of lead in household dust (dust clearance testing) after such work is advisable.  
 Relocate the family to lead-safe housing.

child with a blood lead level of 45 mcg/dL or higher should be referred, if possible, to a pediatrician who is familiar with the pharmacologic management of childhood lead poisoning. This is especially salient as children's blood lead levels have come down so that few physicians have experience using the various available chelating agents, managing their potential side effects, or managing lead encephalopathy. If such a referral is not immediately available, the treating physician may consider consulting with an individual with such experience, such as a pediatrician not in the area, a toxicologist, or a poison control center.

## Chapter 284

## LEARNING DISORDERS

Laura L. Bailet, PhD

### FOUNDATION

#### Definition

The term *learning disability* (LD) represents a broad array of specific learning challenges that significantly impede one's ability to perform at the expected level in an important area of academic performance. LD generally occurs in the context of normal sensory functioning and otherwise normal cognitive capabilities and is not the result of a primary emotional disorder or lack of opportunity.

A formal definition of LD was first delineated in federal law in 1975 as part of the Education for All Handicapped Children Act. That law is now called the Individuals With Disabilities Education Improvement Act (IDEA) of 2004, which specifies regulations pertaining to public education services for persons

with disabilities, and incorporates the following LD definition:

[A] disorder in one or more basic psychological processes involved in understanding or in using language, spoken or written, that may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations, including conditions such as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia and developmental aphasia . . . . The term does not include learning problems that are primarily the result of visual, hearing, or motor disabilities, of mental retardation, of emotional disturbance, or of environmental, cultural, or economic disadvantage. 20 U.S.C. § 1401(30).

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*) definition of Specific Learning Disorder describes “Difficulties learning and using academic skills . . .” (p66). Subtypes include impairment in reading, written expression, and mathematics, which are further specified by severity level. The *DSM-5* also specifies that, although the learning difficulties begin during the school-age years, they may only become fully evident as academic demands increase and thereby exceed the individual’s capabilities. *Dyslexia* and *dyscalculia* are listed as alternative terms for impairment in reading and mathematics, respectively. The term *dyslexia*, first coined by physicians in the late 1800s, is commonly used by clinical professionals to refer to specific reading disability, whereas educators prefer “learning disability.” School personnel often are reluctant to talk about dyslexia, leading to confusion for parents, and often, delays in identification and treatment for affected children. Dyslexia is specifically named as 1 type of LD in the 2004 IDEA, although many educators do not know this and may misinform parents. It can be helpful for pediatricians to talk with teachers and parents about this for clarity. For all practical purposes, the terms can be used interchangeably, as is the case in this chapter. Similar to the federal definition, the *DSM-5* states that, “The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction” (p67). Unlike the federal definition, the *DSM-5* definition does not include receptive or expressive oral language disorders, which are categorized separately.

### Epidemiology

Learning disabilities are quite common, although precise prevalence estimates are difficult to pinpoint. The most commonly cited prevalence estimates range from about 9% to 20% of school-aged children for reading disability, and about 6% for math disability. Estimates vary significantly depending on the severity cutoff used and whether the estimate is based only on the number of public school students identified by IDEA as having an LD for which exceptional student education (ESE) services are provided.

Epidemiologic studies indicate that both boys and girls are affected by LD in significant numbers, with boys having a slightly greater prevalence. Boys are

much more likely to be referred for assessment and treatment, however, because they display a higher rate of concomitant disruptive behavior problems. LD tends to last into adulthood, but early identification and intervention (remedial, accommodative, or both) will optimize outcomes. This is particularly true for reading disability or dyslexia (these terms are used synonymously in this chapter), for which early warning signs and effective treatments as early as pre-kindergarten and the early elementary school years have been thoroughly researched and validated.

LD occurs on a continuum of severity, with most affected individuals experiencing mild to moderate impairment. Learning disabilities are notoriously heterogeneous, and it is not uncommon for an individual to have more than 1 LD, which complicates diagnosis, treatment, and prognosis. In addition, the presenting symptoms will vary according to the child’s age and the developmental demands that are placed on him or her, such that diagnosis can be challenging unless the pediatrician has training and experience with LD across the life span.

### Etiology

Learning disability is considered part of the broad spectrum of developmental disorders. A number of genetic syndromes (eg, Turner syndrome) and childhood medical conditions are associated with an increased frequency of LD, particularly those directly involving the brain (eg, epilepsy, neurofibromatosis type I). In cases in which a child has progressed normally and then begins displaying LD after an acute medical event (eg, stroke, encephalitis), the LD is considered acquired rather than developmental. These cases are rare compared with developmental LD but occur with substantial frequency among children with various medical conditions and events. Diagnostic classification may differ in such cases, but treatment should follow the same approach.

Research indicates that both genetic and environmental factors contribute to developmental LD. Most such research has been conducted on dyslexia and has shown that if an adult has dyslexia, each of his or her offspring has about a 30% to 50% chance of also having the condition. Genetic variants associated with several chromosomes have been identified for dyslexia. Research using various types of postmortem and neuroimaging studies has confirmed neurobiologic differences in brain structure and function for individuals with dyslexia compared with normal readers. The left hemisphere of the brain, and in particular the left posterior quadrant, consistently emerges as the key locus for neuroanatomic anomalies and resultant dysfunctional neural circuits associated with reading impairment, likely reflecting neurodevelopmental aberrations that occur prenatally.

Other risk factors for dyslexia include a history of speech and language disorder or attentional deficits in childhood. Reading is primarily a language-based process, so it is not surprising that reading disability is strongly associated with other types of language impairment. There is substantial literature addressing central auditory and visual processing

disturbances in some children with dyslexia, although the precise nature and significance of these deficits continue to be debated. Achieving reading proficiency is a complex neurodevelopmental process that typically takes several years of focused instruction, effort, and practice. Therefore, children with concomitant attentional deficits, anxiety, or depression may struggle with learning to read simply as a result of an inability to focus as required. Attention-deficit/hyperactivity disorder (ADHD) and dyslexia often co-occur as primary conditions, in which case simultaneous treatment for both disorders is essential to maximize outcomes.

Math disability shows similar degrees of familiarity and heritability, particularly when co-occurring with dyslexia. Neuroimaging research on math disability is sparse compared with dyslexia but shows a more bilaterally distributed pattern that includes both posterior and frontal cortical foci. Math disability often co-occurs with ADHD, reading disability, and written expression disability.

For all types of LD, the presence of any of these risk factors may also be exacerbated by inadequate exposure in early childhood to high-quality language and learning experiences at home and in child care, or low-quality academic instruction. On the other hand, the presence of these risk factors does not forebode a poor response to intervention. On the contrary, neuroscience research shows that emphasizing, from birth, key language and literacy milestones and home and child care activities to support their development has a significant positive effect on early brain development and later reading success for all children. Pediatric programs such as Reach Out and Read (ROR) are based on and contribute to this research. Particularly in the context of programs such as ROR and high-quality early literacy activities in child care or preschool settings, most children at risk for LD will make good progress if identified and treated early, regardless of etiology.

## DIAGNOSIS

### Signs and Symptoms

The major presenting complaint that should raise concern about a possible LD is in a child who shows normal capabilities in most developmental areas and significant discrepancies in a set of specific skills. It is important to pursue diagnosis and intervention for LD as early as possible. Research on reading development and dyslexia indicates that children must acquire reading proficiency by the end of third grade to have a high probability of future academic success. The prime window of opportunity for effective targeted intervention is from preschool through third grade. Beyond that time, remedial intervention is much more costly in terms of time and money and has diminishing returns. Although it is never too late for a person to learn to read, the earlier appropriate instruction begins, the better. The same is likely true for all types of LD, although there is less research from which to draw solid conclusions. Core symptoms of reading, mathematics, and written expression disorders are shown in Table 284-1, Table 284-2, and Table 284-3. A more comprehensive list of symptoms by cognitive/developmental category is available from the National Center for Learning Disabilities.

### Differential Diagnosis

The primary differential diagnoses for LD include ADHD and generalized intellectual impairment. Further complicating the differential diagnosis and treatment planning is the frequent comorbidity of these various conditions (especially LD and ADHD), for which a comprehensive evaluation by an appropriately trained examiner is critical. For the growing number of American children whose first language is not English, their academic difficulties may or may not have an LD component. Again, a thorough evaluation that includes an examiner with expertise in bilingual learning issues is essential in developing an appropriate education plan.

**Table 284-1** Signs and Symptoms of Reading Disability (Dyslexia)

GRADE	DIFFICULTY WITH
<i>Pre-Kindergarten–Grade 1</i>	Letters versus pictures or numbers Letter names and letter sounds Simple, high-frequency words (eg, <i>cat, boy, who</i> ) Rhyming Separating and blending sounds within words
<i>Grades 2–5</i>	Phonics Automatic word recognition Reading aloud Spelling Sounding out longer words Longer reading and writing assignments Reading speed
<i>Grades 6 and Above</i>	Reading comprehension Skills listed for grades 2–5 Written expression skills Learning a foreign language

### Diagnostic Approach and Procedures

A formal LD diagnosis typically does not occur until a child is 6 years of age or older because a major defining characteristic is persistent impairment in an academic skill. Diagnosis at an earlier age should be considered tentative, with frequent reevaluation to clarify whether the cognitive pattern of concern is persisting. A diagnosis of LD is made on the basis of clinical and academic history and the results of a

comprehensive evaluation using a battery of standardized cognitive, language, academic, behavioral, and emotional measures. The goals of the evaluation are to rule out other plausible causes for the learning problem, document specific patterns and severity of learning deficits, and identify significant comorbid conditions. An equally important outcome is the identification of learning strengths, from an intervention planning standpoint and for the affected individual's

**Table 284-2** Signs and Symptoms of Mathematics Disability

GRADE	DIFFICULTY WITH
<i>Pre-Kindergarten–Grade 1</i>	Names of written numerals 1-to-1 correspondence Rapid recognition of set size (eg, set of 3, set of 5) Concepts of <i>more</i> , <i>less</i> , and <i>equal to</i> Concepts of addition and subtraction Meanings of math symbols
<i>Grades 2–5</i>	Memorizing simple addition and subtraction facts, 0–9 Memorizing addition and subtraction facts, 0–20 Concept of place value Addition and subtraction with regrouping Relationships among numbers and strategic counting (eg, 2's, 5's, 10's) Word problems Concepts of time, money, and measurement Concepts of fractions and decimals Concepts of multiplication and division
<i>Grades 6 and Above</i>	Memorizing multiplication and division tables Skills listed for grades 2–5 Interpreting and creating charts and graphs Complex word problems Abstract geometric and algebraic concepts Math applications for personal finance (eg, calculating sales tax, interest rates)

**Table 284-3** Signs and Symptoms of Written Expression Disability

GRADE	DIFFICULTY WITH
<i>Pre-Kindergarten–Grade 1</i>	Writing own name Writing all alphabet letters Copying Spatial aspects of writing (eg, writing on the line, spacing between letters and words) Spelling of simple sight vocabulary and words that follow basic phonics or orthographic patterns
<i>Grades 2–5</i>	Handwriting and copying Written grammar Spelling Basic aspects of written composition (eg, introductory or concluding sentences; logical sequence of sentences)
<i>Grades 6 and Above</i>	Basic rules of written composition (eg, punctuation, capitalization) Skills listed for grades 2–5 Taking notes from lecture Paragraph and essay structure Different styles and purposes of writing Complex grammar structures Use of cohesive ties between sentences and paragraphs (eg, pronouns, connector terms such as <i>however</i> , <i>therefore</i> , <i>in contrast</i> ) Editing and proofreading

emotional well-being. Pediatricians are crucial in identifying children who may have LD, but a formal psychological evaluation is required to establish a firm diagnosis.

Through IDEA, public school systems are required to provide, at no charge, evaluations of both public and private school students for whom there are concerns of possible LD. Parents sometimes prefer to access private resources for such evaluations, which may provide a more complete picture of the child's learning profile and more comprehensive treatment planning support. Such evaluations can be expensive and typically are not covered by health insurance, but they are often invaluable in elucidating the child's learning problem. IDEA regulations for LD are complex. Parents should educate themselves on these laws through online resources ([www.wrightslaw.com](http://www.wrightslaw.com)). They should also ask their physicians how closely they work with local schools, and whether they will help the family find appropriate therapists or tutors after completion of the evaluation. Pediatricians may also fulfill this function with families by getting to know local psychologists and remedial learning specialists who specialize in assessment and treatment for LD.

The reauthorization of IDEA in 2004 included sections on an additional approach to addressing educational needs of struggling learners, called *response to intervention* (RTI). RTI is an educational framework with multiple tiers of progressively more intensive instructional support, based on student need, that is implemented in the regular classroom context. Specific practices vary by state, but in general students who are not making satisfactory progress in a critical learning skill (eg, reading, math, behavior) should receive targeted, small group extra instruction for some length of time, with frequent, brief assessments to gauge progress. With adequate progress, the targeted instruction ends; with poor progress, more intensive instruction should ensue. Although RTI was never intended to impede the timely provision of an individual comprehensive evaluation to determine eligibility for ESE services, it is widely recognized that this often occurs. Further complicating the picture is that teachers often are left to determine for themselves what type of intervention to provide, how often, and for how long. Time slips by, and parents see their children falling further behind. Pediatricians should let parents know that, by law specified through IDEA, RTI cannot be used to delay or deny the comprehensive evaluation of a child with a suspected disability, and that the parent has the right to request the evaluation at any time. The school can deny the request but must provide written notice of the decision, at which point the parent can challenge it by requesting a due process hearing.

### Laboratory Findings

Laboratory or other medical studies are generally not needed to diagnose LD. Such studies may be needed to rule out underlying medical conditions that may cause or contribute to the learning problem. For example, it is essential that any child who is struggling in school have comprehensive vision and hearing evaluations to rule out sensory impairment.

Additional medical studies should be performed only if the child presents with symptoms other than possible LD that would warrant such studies. Genetic and neuroimaging studies generally are not necessary for diagnosing LD or guiding treatment planning.

### Classification

The psychologist who completes the evaluation should provide a specific diagnosis and classification. This can vary depending on whether the psychologist is working within a public school system, which uses IDEA classifications, or in a community setting, where DSM-5 classifications are likely to be used. Under IDEA, public schools must determine whether a child meets criteria for "specific learning disability," compared with other covered conditions (eg, intellectual or sensory impairment) or with no covered condition. Many children have LDs that do not meet the threshold of criteria for IDEA classification and associated educational services. A particularly challenging aspect of LD identification or diagnosis is the aptitude and achievement discrepancy issue. Although virtually all practitioners agree conceptually that LD is characterized by such discrepancies, establishing specific psychometric criteria remains controversial from a theoretical, statistical, and ethical perspective. One result of this ongoing controversy is that individual states differ in how they operationalize IDEA regulations, such that a child may meet criteria for LD services in 1 state, but not another. It is this very issue that often brings families to their pediatrician for advice. Having knowledge of available community resources, books, and Web sites on LD is a valuable service that pediatricians can provide in such cases.

### MANAGEMENT

Learning disability is not a disease, and thus there generally is no cure. Rather, LD is a cognitive condition to be managed proactively to the extent possible, to limit its adverse effects and maximize the child's opportunities to achieve at the level of his or her potential. The keys to successful outcomes are early identification and appropriate intervention, accommodations when needed, a balance of focus on the child's learning weaknesses and strengths or interests, and strong parental advocacy when the child is young and self-advocacy as the child becomes older. LD symptoms tend to remain present throughout the life span. Expanding accommodation options and a growing awareness of the strengths that individuals with LD often possess, however, mean that higher education and employment options are many.

### Treatment Approach

Robust scientific evidence now supports interventions for reading disability. Much of this evidence was synthesized in the report to Congress of the National Reading Panel in 2000. Five critical skills were identified that support reading proficiency by the end of third grade for all children: phonemic awareness, phonics, vocabulary, fluency, and comprehension. For those with dyslexia, 80% or more have a core deficit in phonemic awareness, which refers to the ability to

identify and work with individual speech sounds that make up words. Through extensive research, several critical instructional features have been established for dyslexia treatment. Reading instruction should be explicit, sequential, systematic, and intensive in order for struggling readers to make adequate gains. A critical component for long-term success is explicit instruction in “cracking the code,” that is, understanding how speech sounds map onto written symbols (letters). Two of the 5 critical skills identified by the National Reading Panel, phonemic awareness and phonics, are the essential starting point for teaching children with dyslexia to read and spell. In addition, instruction must focus explicitly on developing automatic word recognition. Many research-based remedial reading programs are widely available and effective in increasing word decoding and word recognition skills for students with dyslexia, when used as designed and with sufficient frequency and intensity. Intervention incorporating such instructional methods has been shown through functional neuroimaging to actually change brain function toward a more normal state. The best outcomes from these studies were associated with individual or small group instruction. The effect on text-level reading fluency and comprehension is variable but tends to be better when intervention is begun early.

Research on intervention for other types of LD is less well developed, but several important instructional principles have emerged (see Box 284-1). Individual or small-group instruction that incorporates these strategies will likely be more effective than large-group instruction. More instructional time also is central to catch-up growth for students with LD, which in most cases should be the academic goal.

Another important component of LD treatment involves accommodations (see Box 284-2). Technology plays a major role in accommodations, and new options are rapidly becoming available. Decisions about instructional supports and accommodations should be made in the context of the effect and severity of the LD at a given time in the child’s life, rate of progress with remedial intervention, and the child’s perspective. Older children and adolescents with LD may be uncomfortable with visible supports or modified academic requirements. Choosing less visible accommodations may make the most sense in such situations. Striking the proper balance is important and will likely need adjusting during different developmental stages. Finally, efforts to develop the attributes of persistence and resilience in children with LD will help them manage their challenges, cultivate goals and hope for their future, and support a favorable prognosis. Pediatricians’ words of encouragement and ability to take the longer-term view can be highly encouraging for families in this regard.

### When to Refer

If there are concerns about LD, the child should either undergo an evaluation through the public school system or be referred to a psychologist with current LD expertise working in the community. Even if the child has had a public school evaluation, a second opinion

### BOX 284-1 Common Instructional Supports for Learning Disabilities

- Explicit instruction describing the task and method for completing it
- Explicit explanation and demonstration of appropriate problem-solving strategies
- Properly sequenced instruction and step size from simpler to more complex tasks or concepts
- Emphasis on concepts that are confusing (eg, for ending consonant blends *nd* as in *land*, and *mp* as in *lamp*: color-coding the letters of interest; over-articulating and directing attention to the mouth when pronouncing words with *nd* versus *d*, or *mp* versus *p*; explicitly comparing and contrasting written word pairs: *lap* – *lamp*, *lad* – *land*, *lip* – *limp*, *led* – *lend*)
- Shortened assignments
- Task structuring to reduce complexity (eg, spelling test with words that follow only 1 spelling pattern, such as short *a*; fewer math problems on a page)
- Multisensory teaching strategies (visual, auditory, tactile and kinesthetic)
- Concrete examples of abstract concepts (eg, manipulative materials to represent numeric concepts such as addition with regrouping)
- Immediate corrective feedback
- Frequent repetition and review
- Multiple-choice rather than recall testing format
- Cue cards to reduce memory load (alphabet strip on child’s desk as he is learning to write letters; index card with steps for subtraction with regrouping)
- Separation of longer assignments into several smaller steps
- Graphic organizers (eg, tree diagrams to represent hierarchic concepts; visual mnemonic images)
- Demonstration of problem-solving strategies (eg, identifying known from unknown key issues; developing sequential steps toward a solution)

by another psychologist may be helpful. School-based evaluations often focus primarily on determining whether the child qualifies for services under the IDEA, and parents may have questions or concerns that have not been addressed.

## ONGOING CARE

### Follow-Up

After a diagnosis has been made and intervention is underway, it is important to follow up on the child’s progress. With most LDs, one should expect an educational program of sufficient intensity to achieve catch-up growth. Simply holding steady in one’s skills is neither sufficient nor justified in most cases. Quick, targeted assessment of key skills being taught should occur at least every few months so that timely adjustments in teaching methods and intensity can be made. Periodic comprehensive reevaluation every few years is advisable as well to obtain an objective

### **BOX 284-2 Common Accommodations for Learning Disabilities**

- Extra time to complete assignments and tests
- Ability to take tests in a quiet, private room
- Waiver or modification of foreign language requirement
- Computer or electronic keyboard in lieu of handwritten assignments and tests
- Calculator

assessment of progress, adjust the treatment plan according to current needs, and ensure that intervention gains are maintained over time. When parents have evidence that their child's educational needs are not being met by his or her school program, they need to advocate assertively for appropriate changes. Resources that are helpful are listed at the end of this chapter.

Parents should be cautioned about unproven therapies and given information about reputable Web sites and book references. For example, various types of optometric treatments are routinely promoted for LD. The AAP has had a position statement on this topic for many years, which states explicitly that scientific evidence does not support eye exercises, vision therapy, or colored lenses as a treatment for LD.

### **Complications**

The major complication of LD tends to be lack of progress or worsening of the adverse effects. In such situations, further evaluation, or reevaluation is often helpful. Undiagnosed comorbid conditions should be considered, particularly ADHD, along with a review of the nature, intensity, and duration of interventions undertaken. In many situations, remedial therapy or tutoring may be needed over and above services that are provided at school. Students who chronically

struggle and fail academically are at high risk for dropping out of school. The longer a child struggles without proper assistance, the more difficult the academic situation becomes, and the greater the emotional toll on the child and family. Appropriately aggressive intervention and follow-up of progress are therefore paramount.

### **Prognosis**

All but the most severely affected individuals with LD should be expected to complete high school and function independently as adults, with many participating in postsecondary education programs. Individuals with LD can achieve at high levels in all types of employment and professions. Although they may need accommodations throughout their life span, they often display outstanding intelligence, problem-solving skills, persistence, and creativity that are advantageous in the workforce and in adult life. Explicitly acknowledging and nurturing each child's strengths and interests, both within school and through nonschool activities, while also addressing the LD, is essential for preventing debilitating emotional and behavioral difficulties that often arise in response to undiagnosed or poorly treated LD.

### **Prevention**

The keys to LD prevention are early identification, preferably during the preschool years, of children at risk for learning problems; rapid deployment of research-based intervention for children identified as at risk; ongoing progress monitoring and continued intensive intervention as needed; and proactive adjustment of supports as the child becomes older. Pediatricians are ideally suited to lead this effort, owing to their knowledge and surveillance of child development, familiarity with individual patient families, ability to identify science-based versus unproven treatments, and status among parents as a trusted professional.

During the preschool years, guidance on basic child development best practices, such as cautioning against too much screen time and emphasizing the importance of having print materials in the home and reading daily with children, can go a long way toward prevention of problems with kindergarten readiness, which currently affects about 40% of children. LD prevention research has been conducted primarily in relation to dyslexia and reading failure, and results are encouraging. Participation in the ROR pediatric program, previously mentioned, significantly increases oral language skills in low-income preschoolers and the home literacy activities of their parents. ROR begins at 6 months of age, is easy to implement in a pediatric practice, and is highly cost-effective. Preschool children can also be screened on early literacy skills with a tool such as Get Ready to Read (GRTR), which was developed in conjunction with the National Center on Learning Disabilities and is available online, for free, in both English and Spanish ([www.getreadytoread.org](http://www.getreadytoread.org)). Psychometric characteristics are excellent for a screening instrument, and free home literacy activities are on the GRTR Web site, along with other parent-friendly information.

Research using GRTR as a premeasure and a post-measure has shown that intensive early literacy instruction results in significant and sustained early literacy gains. This intervention program is being used with at-risk young learners in hundreds of public and private preschool and kindergarten classrooms in multiple states. Children screened in pediatricians' offices and identified as at risk thus have growing opportunities to receive effective early intervention in their communities. Targeted parent intervention also shows promise for preventing reading problems in kindergarten and beyond.

## Chapter 285 LEUKEMIAS

Veronika Polishchuk, MD; Michael Roth, MD;  
E. Anders Kolb, MD

The incremental increase in survival among children with acute lymphoblastic leukemia (ALL) over the last 50 years is often cited as the great success story in clinical oncology. In the spectrum of childhood ailments, leukemias remain quite rare; but, among childhood malignancies, the leukemias are the most common. Accurate diagnosis and risk stratification are still the first steps and, in many cases, the most important steps toward cure. The role of the pediatrician in leukemia treatment does not usually end with the initial referral to an oncologist. A significant portion of treatment for ALL is done on an outpatient basis, and children should still be seen periodically by their pediatrician throughout treatment for routine care. As the number of long-term survivors among children with leukemias continues to increase, so too will the role of the general pediatrician in their care. An understanding of the biology, treatment, prognosis, and short- and long-term side effects of childhood leukemias will be necessary for primary care physicians of children and adults in the future. This chapter reviews the epidemiologic features, pathogenesis, classification, treatment, prognosis, and outcomes in childhood leukemia.

### EPIDEMIOLOGY

Leukemia remains the most common malignancy of childhood (Figure 285-1) with an annual incidence of 45 cases per 1,000,000 children in the United States. Leukemias account for a quarter of all childhood malignancies. In the United States, more than 3,000 children younger than 20 years of age will be diagnosed with leukemia each year, 80% of which are types of ALL.

The peak incidence of childhood leukemia is approximately 4 years of age, although this peak is due almost entirely to patients diagnosed with ALL. Acute myelogenous leukemia (AML) is equally distributed among patients 0 to 10 years of age, with a slight increase in incidence in adolescence. Acute lymphoblastic leukemia is more common among whites than it is among blacks in the United States, but AML is equally distributed among all ethnic groups. Early reports of worse outcomes for blacks with leukemia have been largely refuted in recent publications. The incidence of leukemia is also slightly higher among boys than it is among girls. The ratio of boys with leukemia to girls with leukemia is greatest during adolescence, particularly in the subset of patients with T-cell ALL.

### LEUKEMOGENESIS

The exact cause of most leukemias is not known, although several predisposing factors and exposures have been identified (Box 285-1). In all likelihood, the causes of most leukemias are multifactorial and

**Figure 285-1** Incidence of cancer types from 1996 to 2002 in children aged 0 to 19 years. Malignancies are classified according to International Classification of Childhood Cancer. Incidence is expressed as rates per 1,000,000 and are age-adjusted to the 2000 United States standard population. CNS, central nervous system. (From *US Cancer Statistics Working Group. United States Cancer Statistics: 1999-2002 Incidence and Mortality Web-based Report Version*. Atlanta, GA: Department of Health and Human Services, Centers for Disease Control and Prevention, and National Cancer Institute; 2005.)

include genetic, immune, infectious, and environmental factors.

### Genetic Factors

The association of leukemia with various constitutional chromosomal abnormalities, the reports of familial leukemias, and several reported karyotypic abnormalities in leukemia cells all suggest that a predisposition to childhood leukemia may be inherited.

Patients with Down syndrome (trisomy 21) have a 15-fold increased risk of developing leukemia when compared to healthy children. Infants with Down syndrome have a high incidence of a transient myeloproliferative phenomenon in infancy and the rare M7, megakaryocytic form of AML. Most of the cases of transient myeloproliferation resolve within a couple months with little or no therapy, although 25% to 33% of children will develop a true leukemia within 2 years of diagnosis. Acute myelogenous leukemia in young children with Down syndrome can usually be treated with less-intense therapy and carries a more favorable prognosis than AML in children without trisomy 21. Older children with Down syndrome carry a risk of relapse similar to that of the general population. Numeric and structural changes in chromosome 21 in leukemia cells are also commonly associated with ALL and AML in otherwise healthy children and adults. Trisomy 21, whether it is present in the germ

### BOX 285-1 Factors Associated With a Higher Risk of Developing Leukemia

#### GENETIC PREDISPOSITION

##### ALL

- Siblings of patient with a childhood leukemia, with a higher risk for a twin
- Down syndrome
- Bloom syndrome
- Ataxia telangiectasia
- Congenital hypogammaglobulinemia
- Neurofibromatosis
- Klinefelter syndrome

##### AML

- Down syndrome
- Fanconi anemia
- Bloom syndrome
- Paroxysmal nocturnal hemoglobinuria
- Wiskott-Aldrich syndrome
- Neurofibromatosis
- Klinefelter syndrome
- Shwachman-Diamond syndrome

#### ENVIRONMENTAL EXPOSURES

##### AML

- Ionizing radiation (therapeutic or environmental exposure)
- Epipodophyllotoxin or alkylator-based chemotherapy

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia.

line or a random event occurring in a hematopoietic progenitor cell, may be the first of 2 mutations leading to an acute leukemia, the second being a random somatic event.

A well-documented high incidence of leukemia exists among children with the autosomal-recessive chromosomal fragility disorders of Bloom syndrome, ataxia telangiectasia, and Fanconi anemia. In these syndromes, the propensity of dividing cells to develop random genetic mutations is likely the cause of the increased incidence of leukemias, as well as other malignancies. Although ALL is reported, both Bloom syndrome and Fanconi anemia are associated more frequently with the development of AML. Additional syndromes associated with an increased risk of AML include Shwachman-Diamond syndrome (abnormal ribosome processing), Kostmann syndrome (severe congenital neutropenia), and dyskeratosis congenita (abnormal telomere maintenance).

The concordance of ALL in monozygotic twins is estimated as high as 50% in the first year of life, with more recent studies suggesting the concordance rate among monozygotic twins to be 15% to 20% after the first year of life. The risk is highest in infancy and diminishes with age. The concordance rate for monozygotic, monochorionic twins with ALL with mixed lineage

leukemia (MLL) fusion gene is greater than 95%. By age 7 years, the risk of leukemia in the unaffected twin is close to that of the general population. Possibly, the concordance is because of a genetic predisposition or a common environmental exposure in infancy. In fact, a 1.3- to 4-fold greater risk of developing leukemia is found among singleton siblings of children with leukemia. However, an alternative exists for the exceptionally high concordance rate among twins. By sequencing the leukemia fusion gene in 3 twin pairs, Ford and colleagues demonstrated that the rearrangement in the leukemia fusion gene in each twin pair was identical. These data suggest that transplacental transfer of leukemia cells in monozygotic twins may also contribute to the concordance.

Recent genome-wide association studies in children with ALL identified germ line polymorphisms in 2 genes, *IKZF1* and *ARID5B*, that were associated with an elevated risk of developing childhood ALL. Polymorphisms in *ARID5B* are associated with hyperdiploid ALL, a subtype with excellent prognosis. Genetic alterations in *IKZF1* have been associated with high-risk ALL and generally portend a poor prognosis. Children with immunodeficiencies are also at an increased risk for lymphoid malignancies.

### Environmental Factors

The risk of leukemia, mainly AML, after exposure to ionizing radiation is well established. The first report of the association between ionizing radiation and leukemia came in 1944 in a publication citing a 9-fold increase in the incidence of leukemia among radiologists when compared with other physicians. Subsequently, a 10- to 20-fold increased risk of leukemia was reported among the survivors of the atomic bomb detonations in Hiroshima and Nagasaki in 1944. Finally, an increased incidence in leukemia was reported in patients exposed to radiation either in utero or for treatment of tinea capitis, ankylosing spondylitis, or thymic hyperplasia.

Studies suggest a role of maternal infections in the pathogenesis of leukemia in children (reviewed in 28 studies); however, currently definitive evidence supporting this hypothesis is lacking.

Several studies have examined the DNA derived from neonatal Guthrie cards in singleton children diagnosed with ALL. In the first report, Gale and colleagues identified the t(4;11) translocation (typically associated with infant ALL) in the diagnostic specimens and Guthrie cards in children 2, 5, and 6 years old at diagnosis of their leukemia. Several subsequent reports analyzing dried blood spots using polymerase chain reaction-based approaches probing for specific mutations, clonal immunoglobulin rearrangements, or T-cell receptor rearrangements confirmed these results and are thoroughly reviewed by Taub and Ge. Whether the abnormal cells detected on the Guthrie cards reflect a leukemic clone or a preleukemic cell is unknown. In many of the cases examined, evidence of an abnormal clone was found in the Guthrie cards of children 5 to 13 years old. This long latency period argues for the role of postnatal events in the pathogenesis of childhood leukemias. Greaves and colleagues speculate that

the mutation detected in the Guthrie cards is the first of 2 genetic hits required for a leukemic transformation. In support of this theory is the fact that a high concordance rate of leukemias exists among twins with *MLL* chromosome band 11q23 fusion genes, but only a 5% concordance rate among twins with the *ETV6/RUNX1* (*TEL/AML1*) mutation. These data suggest that, in certain subtypes of ALL (*ETV6/RUNX1* and hyperdiploid ALL) and AML (associated with t[8;21]), the first preleukemic event occurs in utero, but postnatal events are necessary for the transformation to a leukemic phenotype. A recent study using whole-genome sequencing in monozygotic twins with ALL identified the *ETV6/RUNX1* fusion as the only shared mutation between leukemia cells in an infant pair; supporting the role of the *ETV6/RUNX1* fusion as the initiating defect. In addition, this hypothesis is possibly supported by one study's description of late relapse *ETV6/RUNX1* ALL in which the recurrence is actually a second *de novo* ALL derived from an identical premalignant stem cell.

To identify the possible prenatal and postnatal insults necessary for the leukemic transformation, investigators have examined the role of toxins, electromagnetic fields, pesticides, nitrites, population mixing, seasonal and climatic variations, birth weights, socioeconomic status, breastfeeding, and maternal history of fetal loss in leukemogenesis. However, little, if any, conclusive evidence exists. Equally unclear is the role of in utero and childhood infections in the pathogenesis of childhood leukemia. In recent case-controlled studies, infections in childhood were associated with both a protective effect against leukemia and an increased risk for leukemia. Most studies evaluating childhood vaccination and leukemia demonstrated a protective effect, whereas one study suggested an increased risk for childhood leukemia after measles-mumps-rubella vaccination. Numerous other trials reviewed by McNally and Eden demonstrate only nonsignificant effects after childhood immunizations. Using child care attendance as a surrogate for infectious exposures in children, no studies to date demonstrate an increased risk of leukemia among children in child care. On the contrary, 5 recent case-controlled studies demonstrate a protective effect of child care attendance. No study to date identifies evidence of viral genomic inclusion in leukemia cells. The data suggest that exposure to certain infections may provide a protective effect against leukemias, presumably through early development of a mature and experienced immune repertoire. The data may also suggest that exposure to infections in children with a relatively naïve immune system later in childhood may increase the risk for leukemia.

The possible environmental contributors to leukemia risk in childhood are reviewed only briefly earlier in this chapter. With improvements in genomic technology, the molecular pathways involved in the development of childhood leukemia are being increasingly defined; however, the interplay between genetic predisposition and environmental influences in leukemogenesis is likely to be complex and multifactorial. Ultimately, whether the cause is from low-level radiation, infection, toxin exposure, or an unknown carcinogen, DNA

damage and inadequate DNA repair is the initial insult. Subsequently, 1 or more events, which may be influenced by environmental exposures, initiate the transformation to a malignant phenotype. The future of preventive medicine in childhood leukemia relies on further characterization of molecular events in leukemogenesis and the influence of environmental forces on these events.

## CLINICAL MANIFESTATION

### Presenting Signs and Symptoms

The presenting clinical features of childhood leukemias (Table 285-1) reflect the uncontrolled proliferation of malignant cells leading to replacement and suppression of normal hematopoietic progenitor cells and infiltration into extramedullary spaces. Symptoms often accumulate in days to weeks, culminating in some event that brings the child to medical attention. A common question of parents and practitioners alike is whether the leukemia might have been caught sooner. Many researchers would argue that the biological characteristics of the leukemia are determined

at the moment the first leukemia cell transforms. Signs of aggressive disease, such as a high white blood cell (WBC) count, extramedullary disease, or significant cytopenias may reflect the underlying biological features of the disease rather than timing of diagnosis.

The common clinical signs and symptoms of childhood leukemias are similar to common complaints among children with benign illnesses. Fever is present at diagnosis in most children with leukemia. Only subtle findings may exist on examination or in the history distinguishing fever in a child with leukemia from fever in normal children. Complaints of bone pain (manifesting as a limp in younger children), significant and diffuse lymphadenopathy, hepatosplenomegaly, pallor and petechiae, unexplained ecchymoses, and bleeding are all signs that often trigger further studies. More subtle and less specific complaints of fatigue and anorexia typically warrant close follow-up. Laboratory studies are typically necessary to corroborate clinical evidence.

### Laboratory Findings

The WBC count may be normal, increased, or decreased in a patient newly diagnosed with leukemia, and blasts may or may not be present on the peripheral blood smear. Anemia and thrombocytopenia are common, but not always present. In other words, although a complete blood count is certainly the first laboratory study necessary in the diagnosis of leukemia, a normal complete blood count result does not rule out leukemia. Continued close follow-up or referral to a hematologist should be guided by clinical evidence and laboratory findings.

Other abnormal laboratory findings include measures of tumor burden and cell turnover—increased potassium, increased phosphorus, decreased calcium, increased uric acid, and increased lactate dehydrogenase. These findings are hallmarks of the tumor lysis syndrome. Usually most severe after administration of chemotherapy, signs of tumor lysis may be present at diagnosis because of rapid proliferation and destruction of leukemic cells. Children at risk for significant electrolyte abnormalities and even renal failure are those with evidence of high tumor burden—high WBC count, massive organomegaly, and mature B-cell leukemia (Burkitt type), especially if an extramedullary tumor mass is present. Preemptive management decreases clinical manifestations and secondary consequences of tumor lysis syndrome in childhood leukemias.

Mediastinal masses are present in 5% to 10% of children with leukemia, especially older boys, who are more likely to have a T-cell leukemia. A chest radiograph is necessary in all children suspected of an acute leukemia and should be performed before administering anesthesia for any procedures. Though not required in the diagnostic evaluation of childhood leukemia, radiographs of long bones will often demonstrate evidence of leukemic infiltration of the periosteum and bone. Patients with particularly high leukemic cell burdens may seem osteopenic; others may demonstrate signs of subperiosteal new bone formation, radiolucent bands in the metaphysis (leukemic lines), discrete osteolytic lesions, and growth arrest lines.

**Table 285-1** Common Clinical and Laboratory Findings Present at Diagnosis in Children With Leukemia

	ALL (%) <sup>a</sup>	AML (%) <sup>b</sup>
<b>CLINICAL FEATURES</b>		
Fever	61	34
Pallor	55	25
Petechiae, purpura, bleeding	48	33
Anorexia or weight loss	33	22

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia.

<sup>a</sup>Miller DR. Acute lymphoblastic leukemia. *Pediatr Clin North Am.* 1980;27(2):269–291.

<sup>b</sup>Choi SR, Simone JV. Acute nonlymphocytic leukemia in 171 children. *Med Pediatr Oncol.* 1976;2(2):119–146.

### Extramedullary Leukemia

Approximately 5% of patients will have evidence of disease in the central nervous system (CNS) at diagnosis. However, few children will have symptoms of disease at diagnosis, including vomiting, headache, and lethargy. Papilledema and cranial nerve palsies, which are significant signs of extensive CNS involvement, are not common. Cranial nerve palsies are typically reflective of meningeal infiltration of leukemic cells rather than increased intracranial pressure. Children at greatest risk for CNS disease are those with mature B-cell leukemia, T-cell ALL, those younger than 2 years of age, and those with monoblastic forms of AML. Painless enlargement of 1 or both testicles has been reported in fewer than 2% of boys diagnosed with leukemia and is more common in ALL (particularly T-cell ALL) than AML.

### Chloromas

Chloromas, or granulocytic sarcomas, are solid collections (tumors) of malignant cells in patients with AML. Chloromas can occur anywhere, including the skin, CNS, and bones. Rarely, chloromas can occur independently of or before evidence of bone marrow disease.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of individual or concurrent cytopenias includes several common infectious and noninfectious diseases of childhood (Box 285-2). The spectrum of signs and symptoms of childhood

leukemias mirrors the spectrum of many more common illnesses. Differentiating childhood leukemia from these other illnesses often requires either periodic reassessment of clinical and laboratory parameters of disease or, in cases in which the index of probability is sufficient, a more definitive bone marrow aspiration and biopsy. If the leukemic cell burden is sufficient to elicit clinical symptoms, then findings on a bone marrow evaluation will not be subtle. Identifying children with signs and symptoms severe enough to warrant a bone marrow evaluation (often requiring anesthesia in younger children) can be challenging. In children with atypical findings of common diseases, the general pediatrician's best tools are a high index of suspicion and frequent follow-up. An acute leukemia cannot hide for long before declaring itself.

Many illnesses more common than leukemia produce fever, rash, lymphadenopathy, hepatosplenomegaly, mild cytopenias, or lymphocytosis. The appearance of atypical and variant lymphocytes on the peripheral blood smears of children with infections such as Epstein-Barr virus, pertussis, and paraptosis often bring leukemia into the differential diagnosis. Diseases such as systemic lupus erythematosus and juvenile idiopathic arthritis may be associated with bone or joint pain and cytopenias that are indistinguishable from an acute leukemia. For many diseases, eliminating leukemia from the differential diagnosis becomes of paramount importance in specific diseases that require use of corticosteroids (systemic lupus erythematosus, juvenile idiopathic arthritis, immune thrombocytopenia purpura, hemolytic anemia, and even infectious processes precipitating an acute asthma exacerbation). In these instances, if leukemia is possible or probable, then referral to an oncologist may be necessary. Inadvertent administration of corticosteroids may impair or delay the diagnosis of leukemia and may necessitate more intensive high-risk chemotherapy for children with otherwise standard-risk disease.

### BOX 285-2 Differential Diagnosis of Childhood Leukemia

#### NONMALIGNANT DISEASES

- Juvenile idiopathic arthritis
- Systemic lupus erythematosus
- Infectious mononucleosis
- Immune thrombocytopenia purpura
- Aplastic anemia
- Pertussis, paraptosis
- Benign lymphocytosis
- Leukemoid reaction
- Sepsis
- Osteomyelitis
- Hemophagocytic histiocytosis
- Kawasaki disease
- Hemolytic uremic syndrome
- Thrombotic thrombocytopenic purpura
- Multifocal recurrent osteomyelitis

#### MALIGNANCIES

- Neuroblastoma
- Ewing sarcoma
- Rhabdomyosarcoma
- Lymphoblastic lymphoma

## CLASSIFICATION

Leukemias are a heterogeneous group of disorders classified by immunophenotype and subclassified based primarily on prognostic features. Leukemias can be classified as acute or chronic and lymphoblastic or myelogenous. In a normal marrow, blasts, which are hematopoietic progenitor cells, make up less than 5% of the total nucleated-cell population. Rarely are these cells found in the peripheral blood, except in instances of significant infection, bleeding, or a malignant process occupying the marrow space, including metastatic disease from solid tumors. According to the 2008 World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia, the acute leukemias are defined as a clonal expansion of hematopoietic progenitor cells (blasts) such that the number of these cells exceeds 25% of the total nucleated-cell population in the marrow for ALL or 20% for AML. If known, recurring cytogenetic abnormalities are found in the blast population, a diagnosis of ALL can be made with less than 25% blasts in the bone marrow, and of AML with less than 20%. Acute

myelogenous leukemia can also present with extramedullary disease and minimal or no bone marrow involvement. The expansion of leukemia cells in the confined marrow space and their impingement on normal marrow progenitors is often reflected in the relatively rapid onset of symptoms in patients with acute leukemia. In contrast, in chronic leukemia, a hyperproliferation of mature hematopoietic elements can be found, often in the absence of life-threatening cytopenias. Chronic leukemias have a more insidious onset than the acute leukemias. Although the initial management may not be as problematic, long-term eradication of the disease is more difficult in chronic leukemias.

Acute leukemia cells likely arise from a single, mutated progenitor cell that proliferates, but does not differentiate into a functional mature cell. In the diagnostic bone marrow specimen, the abnormal cells predominate and determine the leukemia type. Classification into myeloid or lymphoid lineages, and good or poor prognosis, is based on morphology, immunophenotype, cytogenetics, and behavior. Acute lymphoblastic leukemia is the most common form of leukemia (Figure 285-2). Subclassification into B precursor, mature B cell, and T cell lymphoblastic leukemias is essential to treatment and prognostic stratification of patients (Table 285-2). The myeloid leukemias (Table 285-3) can be categorized based on cytogenetic and morphologic features. The traditional French-American-British (FAB) system,

which used morphology for classification, has been largely replaced by the WHO system. The WHO system stratifies based on cancer cytogenetics, weighs molecular features of the disease more heavily than morphologic features, and has greater prognostic utility.

ALL, acute lymphoblastic leukemia; NOS, not otherwise specified; WBC, white blood cell.

Immunophenotype

Classification of leukemia by immunohistochemical or immunoflow cytometric detection of lineage-specific antigens allows for a precise and biologically relevant description of the leukemia cells. From the first bone marrow aspiration and biopsy, a crucial distinction between AML and ALL is made. Acute lymphoblastic leukemia is often treated with a 3- or 4-drug induction regimen of limited toxicity, whereas AML is treated with much more aggressive induction regimens. Surface and cytoplasmic antigens differentially expressed on cells of myeloid or lymphoid origin can be used to reliably distinguish AML from ALL and to subclassify within each lineage.

Acute Lymphoblastic Leukemias

Many lymphoid malignancies (B and T lineage) will express terminal deoxynucleotidyl transferase. No

antigen is truly lineage-specific in leukemia samples, and some cases are mixed lineage or undifferentiated, but most B-cell leukemias will express CD10, CD19, CD22, or any combination, whereas T-lineage leukemias will express CD3, CD7, or both. Among 3,073 children enrolled in the ALL-BFM (Acute Lymphoblastic Leukemia, Berlin-Frankfurt-Munster) 86 and ALL-BFM 90 trials, 403 (13%) had T-cell ALL, and 2,690 (87%) had B-cell ALL. The distinction between T- and B-lineage lymphoblastic leukemia is important to prognosis and treatment.

Early-cell ALL arises from a precursor B cell that is too immature to produce cytoplasmic immunoglobulin and that accounts for approximately 60% of all childhood ALL. Most of these immature leukemias express CD10 (common acute lymphoblastic leukemia antigen), CD19, and CD22, but do not express cytoplasmic immunoglobulin. CD10-negative, CD19-positive, CD22-positive early pre-B-cell ALL are derived from an earlier precursor lymphoblast. When found in infants, the CD10-negative early pre-B-cell phenotype is typically associated with rearrangements involving the MLL locus (11q23) and with a poor outcome.

Derived from a slightly more mature clone, the pre-B-cell ALLs express cytoplasmic (but not surface) immunoglobulin, 90% express CD10, and most express CD19, CD22, or both. Pre-B-cell ALL accounts for approximately 15% of all cases of ALL. The t(1;19) (q23;p13) translocation is found in approximately 25% of cases of pre-B-cell ALL, but only 5% of all cases of ALL. This translocation results in a fusion of the *E2A* and *PBX* genes. Despite the adverse prognostic effect of this translocation in older studies, recent intensification of therapy resulted in an improved survival for these children.

Mature B cell accounts for 3% to 4% of all ALL in childhood. Characteristic immunotypic features include the presence of surface immunoglobulin (usually IgM), CD20 (a mature B-cell marker), CD19, and human leukocyte antigen-DR. Cells are invariably CD10 negative. Mature B-cell leukemias are indistinguishable from Burkitt lymphoma with bone marrow involvement. Nearly all of these malignancies are associated with translocations involving the *MYC* oncogene on chromosome 8.

T-cell ALL affects boys predominantly and is more common in adolescence. Although T-cell malignancies account for only 13% of all lymphoid leukemias in childhood, they are diagnosed in nearly 40% of all children 10 to 18 years of age with ALL. When compared with B-cell ALL, patients with T-cell ALL are more likely to have extramedullary disease. Mediastinal mass, testicular involvement, and CNS leukemia are all more common in patients with T-cell ALL. Historically, T-cell ALL is associated with a less favorable prognosis. However, the historical difference in prognosis between T-cell ALL and B-cell ALL has largely been erased because of intensification of therapy for patients with T-cell ALL.

Acute Myelogenous Leukemia

Acute myelogenous leukemia occurs in approximately 1 in 130,000 individuals younger than 20 years of age, accounting for only 16% of all childhood leukemias.

Table 285-3	Classification of Acute Myeloid Leukemia
FAB CLASSIFICATION	PATIENTS
M1 AML without maturation	24%
M2 AML with maturation	23%
M3 Promyelocytic leukemia	5%
M4 Myelomonocytic	27%
M5 Monocytic	10%
M6 Erythroleukemia	2%
M7 Megakaryocytic	7%

AML, acute myelogenous leukemia; APML, acute promyelocytic leukemia; FAB, French-American-British; NOS, not otherwise specified; MDS, myelodysplastic syndromes; MPD, myeloproliferative disorders.

Significant differences can be found in the surface antigen expression among the FAB subtypes of AML (see Table 285-3). The common myeloid antigens used to differentiate ALL from AML are CD13, CD33, CD117, CD14, CD64, glycophorin A, and CD41. CD14 and CD64 are monocytic markers, glycophorin A is an erythroid marker, and CD41 is a megakaryocytic marker.

### Biphenotypic or Mixed Phenotype Acute Leukemia

In 1995, the European Group for the Immunological Classification of Leukemias developed a scoring system of lineage specificity for different markers and later revised the system in 1998. In this system, AML is distinguished from ALL based on a scoring system (Table 285-4). Biphenotypic or mixed-lineage leukemia is defined as a score of 2 or more in 2 separate lineages. Applying the European Group's criteria to 676 patients newly diagnosed with leukemia, Owaidah and colleagues identified biphenotypic phenotypes in 3.4% of children. Among these children, the Philadelphia (Ph) chromosome (17%) and MLL (26%) abnormalities

were common. The more recent 2008 WHO classification includes cytogenetic abnormalities in addition to immunophenotype in its subclassification of acute leukemias of ambiguous lineage.

### Cytogenetic and Molecular Markers

Researchers have hypothesized that for an acute leukemia to develop, at least 2 relatively broad mutations must occur—class I and class II. Class I mutations offer a proliferative or survival advantage (eg, *RAS* or *FLT3* mutations), whereas class II mutations inhibit differentiation. Identification of these mutations not only offers insight into the pathogenesis of an acute leukemia, but these genetic events also significantly influence prognosis. Table 285-5 reviews the common genetic events that are hallmarks of childhood ALL and AML.

### Acute Lymphoblastic Leukemia

**PLOIDY.** An increase in the modal number of chromosomes (>46) can be detected in nearly one-third of newly diagnosed cases of ALL. Hyperdiploidy is associated with increased sensitivity to chemotherapeutic agents in leukemia cells cultured in vitro. Event-free survival in children with hyperdiploid leukemia cells exceeds 75% to 90%, making it a reliable marker of a good prognosis. Specifically, children with simultaneous trisomies of chromosomes 4 and 10 have a 7-year event-free survival in excess of 90%. Unfortunately, children with fewer than 45 chromosomes (hypodiploidy) have a worse prognosis. The event-free survival for children with 33 to 44 chromosomes is 40%, and for children with fewer than 28 chromosomes, the event-free survival is 25%.

In addition to changes in chromosome number, nearly one-third of childhood leukemias will harbor chromosomal translocations independent of ploidy. Included here is a discussion of a few translocations and mutations, each associated with a distinct biological subset.

**MIXED-LINEAGE LEUKEMIA.** Translocations involving the *MLL* gene at 11q23 and more than 30 potential partner chromosomes can be found in 6% of childhood ALL cases. The t(4;11)(q21;q23) mutation resulting in the *MLL-AF4* fusion product is commonly seen in

**Table 285-4** Scoring System From the European Group for the Immunologic Characterization of Leukemias

POINTS	B-CELL ALL	T-CELL ALL	AML
2	cyCD79 cyCD22	cyCD3 or memCD3	MPO

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia.  
*HOX11* overexpression is a common abnormality in T-cell ALL and is identified in 5%–10% of patients.

infant ALL and is associated with an event-free survival of only 20% to 25%. In children older than 1 year of age, the negative effect of *MLL* gene rearrangements on survival is less; however, most protocols will still include these children in a high-risk group despite other features. In T-cell ALL, the t(11;19)(q23;q13.3) translocation fusing *MLL* with the *eleven nineteen leukemia (ENL)* locus on chromosome 19 is associated with a favorable prognosis.

**E2A/PBX.** Pre-B-cell ALL is often characterized by t(1;19)(q23;q13), resulting in a fusion of the *E2A* and *PBX* genes. Pre-B-cell ALL was once thought to be associated with a poor prognosis, but recent studies with more intensive therapies have shown improved survival.

**BCR-ABL.** The Ph chromosome results from a balanced translocation between the long arms of chromosomes 9 and 22 (t(9;22)[q34;q11]), resulting in the fusion of the *BCR* and *ABL* genes. In 3% to 5% of childhood ALL and 20% of ALL cases in adults, the *BCR-ABL* fusion encodes a 185-kDa dysregulated tyrosine kinase responsible for the malignant transformation. A 210-kDa variant is the hallmark of more than 90% of chronic myelogenous leukemias. Ph+ childhood ALL used to be among the most difficult subsets to cure, with a long-term, event-free survival of less than 50%. The incorporation of imatinib, a tyrosine kinase inhibitor, in a recent Children's Oncology Group study led to a 3-year event-free survival of 80%, which is significantly higher than historical controls. Whereas matched-sibling bone marrow transplant for children with Ph+ ALL in first remission used to be the standard of care, current recommendations are to assess children's response to chemotherapy with a tyrosine kinase inhibitor. Newer-generation tyrosine kinase inhibitors (dasatinib, nilotinib) are currently being investigated for children with imatinib-resistant Ph+ leukemia. The hope is that the identification of other biologically targetable molecular markers will also lead to improvements in survival for other children with high-risk disease.

**ETV6/RUNX1 (TEL/AML1).** The t(12;21)(p13;q22) translocation is the most common in pediatric ALL and is identified in up to 25% of B-precursor ALL. Fusion of the *TEL* locus at 12p13 with the *AML1* gene at 21q22 results in a fusion transcript that serves as a co-repressor of *AML1* target genes. Children with the ETV6/RUNX1 translocation do very well with conventional therapy and may be preferentially sensitive to protocols containing augmented therapy with asparaginase. Children with ETV6/RUNX1-positive leukemias tend to relapse late, and salvage after relapse remains excellent.

**IKZF1.** Mutations in the gene *IKZF1* occur in 15% of patients with B cell ALL and are associated with poor overall survival. *IKZF1* encodes IKAROS, a transcription factor that is essential for normal lymphocyte hematopoiesis. Deletions in *IKZF1*, as well as sequence mutations, lead to abnormal expression of IKAROS and abnormal lymphocyte development. Alterations in *IKZF1* are associated with a higher risk of relapse and treatment failure. Mutations in *IKZF1* are often found in Ph+ ALL and Chronic myelogenous leukemia

(CML) in blast crisis. However, mutations are also found in a subgroup of patients with high-risk Ph- ALL whose leukemia cells have gene expression patterns similar to blast cells from children with Ph+ ALL. This may have implications for the use of targeted tyrosine kinase inhibitors in children with ALL and alterations in *IKZF1*. Additional studies are needed to further understand the implications of the effect of mutations in the *IKZF1* gene.

### Acute Myelogenous Leukemia

**PML/RAR $\alpha$ .** One characteristic chromosomal abnormality in childhood AML is the t(15;17) translocation. The resulting chimeric protein, *PML/RAR $\alpha$* , is formed by the fusion of the retinoic acid receptor- $\alpha$  (*RAR $\alpha$* ) gene from chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. The *PML-RAR $\alpha$*  fusion protein suppresses gene transcription and blocks differentiation of myeloid progenitor cells. Retinoic acid may still bind to the abnormal *RAR $\alpha$*  portion of the protein, promoting differentiation.

**CORE-BINDING FACTOR.** Both inv16 and t(8;21) involve subunits of the transcription factor complex core-binding factor (CBF), disrupting the normal functions of this gene. The CBF is a family of heterodimeric transcription factors containing 1 of 3 CBF $\alpha$  subunits (CBF $\alpha$ 1, *AML1* [also known as *RUNX1* or CBF $\alpha$ 2], or CBF $\alpha$ 3) and a common  $\beta$  subunit (CBF $\beta$ ). The CBF $\alpha$  subunits are involved in both DNA binding and interaction with CBF $\beta$ . CBF $\beta$  functions to enhance binding of CBF $\alpha$  and increases the affinities of the CBF $\alpha$  subunits for DNA. Together, the CBF complex is a critical transcriptional activator of genes involved in hematopoiesis and bone development. The inv16(p13;q22) abnormality results in a fusion of the CBF $\beta$  gene and the myosin heavy chain (*MYH11*). The 8;21 translocation involves the CBF $\alpha$  (*AML1*) gene on chromosome 21 juxtaposed with the *ETO* gene on chromosome 8. Disruption of both the CBF $\beta$  gene by CBF $\beta$ -*MYH11* and the CBF $\alpha$  subunit by the *AML1/ETO* fusion leads to deficient transcription of *CBFA-CBFB*-controlled genes and myeloid maturation arrest. As with the *ETV6/RUNX1* mutation, these CBF-related mutations have been found in the Guthrie cards of patients who develop leukemia well into their second decade. The long latency implies that class II CBF-related mutations may be only the first hit in leukemogenesis. Class II mutations altering expression and function of *FLT3*, *c-KIT*, and *RAS* may provide the second hit and a requisite proliferative advantage to preleukemic cells with already-abnormal differentiation signaling. Patients with t(8;21) or inv(16) have a favorable prognosis when treated with intensive chemotherapy. Additional, but unfavorable, abnormalities identified in AML samples include: -5/del(5q), -7/del(7q), inv(3)/t, +8, and complex karyotypes.

**NPM1.** Mutations in the nucleophosmin gene *NPM1* occur in 8% to 10% of children with AML and are associated with a favorable prognosis. *NPM1* encodes a protein involved in ribosome biosynthesis, centrosome processing, and regulation of p53, and mutations in

*NPM1* are often seen in adult patients with AML and other hematologic malignancies. In children, *NPM1* is associated with *FLT3*-ITD; however, favorable prognostic outcomes are only seen in children with mutations in *NPM1* who lack *FLT3*-ITD.

**CEBPA.** Mutations in the CCAAT/enhancer binding protein- $\alpha$  (*CEBPA*) gene occur in 4% to 5% of children with AML and are associated with a favorable prognosis. *CEBPA* encodes a transcription factor that plays an essential role in terminal granulocytic differentiation. Ho and colleagues reported that in 847 children with AML, the presence of a *CEBPA* mutation was associated with significantly improved 5-year event-free survival (70% vs 38%,  $p = 0.015$ ).

**FLT3-ITD.** Point mutations and internal tandem duplications (ITDs) in the FMS-like tyrosine kinase 3 (*FLT3*) gene occur in approximately 15% of children with AML, and *FLT3*-ITD is associated with a poor prognosis. *FLT3* is a tyrosine kinase whose downstream signaling regulates proliferation, differentiation, and apoptosis. Mutations in *FLT3* often lead to constitutive activation of the receptor, and a *FLT3*-ITD ratio/wild-type allelic ratio greater than 0.4 is associated with progression-free survival of less than 20%. Studies are currently investigating the efficacy of tyrosine kinase inhibitors in children with *FLT3*-ITD.

## TREATMENT OF ACUTE LYMPHOBLASTIC LEUKEMIA

### Risk-Stratified Therapy

Before the 1950s, no classification system existed for childhood leukemias. However, regardless of the myeloid or lymphoid origin of the disease, childhood leukemias were uniformly fatal within months of diagnosis. Djerassi and colleagues were the first group to attempt chemotherapy as a means to treat childhood leukemia. Initial trials with folic acid only made the disease worse; thus, an antagonist of folate metabolism, aminopterin (a methotrexate analog) was used instead to induce the first temporary responses. Subsequently, 6-mercaptopurine (6-MP) and prednisone were tried, both as single agents. Responses, but not cures, were observed. Nonetheless, from this point on, pediatric leukemia trials evolved, each sequential trial expanding from the success and failures of previous trials. Today, risk-adapted therapies, based on clinical features (age, WBC count, and response to induction therapies) and biological features (ploidy and mutations of known prognostic significance), are used to maximize response and cure rates while minimizing long-term side effects (Table 285-6).

Table 285-6

Common Prognostic Features of the Acute Leukemias<sup>a</sup>

	CLINICAL FEATURES	CYTOGENETICS AND MUTATION STATUS
B-cell-precursor ALL	<b>Favorable</b> Age between 1 and 9.99 years	<b>Favorable</b> t(11;22)(p13;q22), ETV6/RUNX1 fusion Hyperdiploidy (>50 chromosomes) Trisomies 4, 10, and 17
	<b>Unfavorable</b> Age >10 years Initial WBC count >50,000/mcL Poor response to induction therapy End induction minimal residual disease Extramedullary disease	<b>Unfavorable</b> MLL rearrangements in infants
T-cell precursor ALL	<b>Favorable</b> Good response to steroids <sup>b</sup>	<b>Favorable</b> HOX11 overexpression t(11;19) MLL-ENL fusion
	<b>Unfavorable</b> Poor early response to treatment Low-intensity chemotherapy regimens	<b>Unfavorable</b> —
AML	<b>Favorable</b> Acute promyelocytic leukemia AML in Down syndrome	<b>Favorable</b> t(8;21) AML1-ETO fusion inv(16) or t(16;16)(p13;q22) t(15;17)(q22;q21), APML/RAR $\alpha$ fusion CEBPA mutation NPM1 mutation
	<b>Unfavorable</b> WBC count >100,000/mcL Secondary AML or AML after MDS	<b>Unfavorable</b> Monosomy 7 (7q-) FLT3-ITD

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; MDS, myelodysplastic syndrome; WBC, white blood cell.

<sup>a</sup>Adapted from Pui CH, Schrappe M, Ribeiro RC, Niemeyer CM. Childhood and adolescent lymphoid and myeloid leukemia. *Hematology Am Soc Hematol Educ Program*. 2004;118–145.

<sup>b</sup>Adapted from Schrappe M. Evolution of BFM trials for childhood ALL. *Ann Hematol*. 2004;83(Suppl 1):S121–S123.

Patients between 1 and 9.99 years of age with an initial WBC count less than or equal to 50,000/mcL are classified as standard risk according to National Cancer Institute and Rome criteria. Children younger than 1 year of age and older than 10 years of age or children with an initial WBC count of more than 50,000/mcL are classified as high risk. In many multi-institutional, international cooperative group studies, age and initial WBC count have proven to be reliable and independent predictors of prognosis. Other clinical features used to stratify therapy include gender, leukemia phenotype, and response to initial therapy. Multiple trials have shown the prognostic value of assessing the bone marrow for minimal residual disease (MRD) both during and at the end of induction therapy. Children with MRD at the end of induction (presence of as few as 1 leukemia cell per 10,000 mononucleated cells) have a poorer prognosis, and their therapy is intensified in an attempt to improve survival (definition of induction and the timing of measurement of MRD is often protocol-dependent and may differ among protocols). Children with ALL who fail to go into remission after induction chemotherapy have a very poor prognosis, with overall survival less than 35%, even with intensified therapy. Recently, the Children's Oncology Group included an additional risk stratification for children with certain high-risk presenting features, as well as those with poor response to initial induction chemotherapy. The goal is to alter and intensify therapy for these children classified as very high risk in hopes of improving outcomes. Girls seem to have a more favorable prognosis than boys; however, recent studies showed less of a disparity in overall survival between genders. The reason for these gender differences is not known.

Leukemia cells that express aberrant myeloid markers, but do not meet strict criteria for biphenotypic leukemia, have historically yielded inferior outcomes; however, this effect is abrogated in recent trials. T-cell phenotype is associated with an inferior outcome, although the clinical features of older age, male gender, and extramedullary disease often associated with T-cell ALL may partly account for the greater risk for relapse. However, with T-cell directed therapy, which includes intensive asparaginase and dexamethasone, recent studies have shown survival greater than 85% for this population. The identification of leukemia cells in the CNS disease at diagnosis continues to be an adverse prognostic feature of childhood ALL despite attempts to intensify CNS-directed therapy.

Response to induction therapy is predictive of outcome and is used to stratify children for more intensified therapy when necessary. At the end of the initial cycle of chemotherapy known as induction, the presence of MRD is associated with significantly poorer outcomes compared with children who have less than 0.01% leukemia cells in the bone marrow. Children with more than 1.0%, 0.1% to 1.0%, and less than 0.01% leukemia blast 29 days after starting chemotherapy had a 5-year event-free survival of 30%, 49%, and 59%, respectively, compared with 88% for children who did not have MRD. Among children with a

slow early response to induction therapy, those who receive intensified therapy will have an improved outcome when compared with those who remain on standard therapy.

### Principles of Treatment

Leukemia cell infiltration in marrow space and other organ systems in children newly diagnosed with ALL may result in pancytopenia, as well as many systemic symptoms. Resolution of symptomatic disease and recovery of normal bone marrow function can only be achieved with the administration of potentially myelosuppressive and immunosuppressive chemotherapy. Therapy is often divided into phases of remission induction, consolidation with extramedullary disease treatment or prophylaxis, and maintenance. The timing, number, and chemotherapy components of each phase may differ between protocols, but the principles of therapy are similar. Remission induction is achieved in most cases with 3 drugs (vincristine, asparaginase, and a corticosteroid) or 4 drugs (addition of doxorubicin). The goal is to induce a complete remission, defined as the reduction of the leukemia cell burden below 5% in the bone marrow after recovery of normal blood counts. With current chemotherapeutic regimens, remission induction is possible in more than 95% of children with ALL. Many protocols follow the induction phase with a consolidation phase heavy in antimetabolites to secure or consolidate the remission.

Delayed intensification is a second phase of intensified chemotherapy used by some cooperative groups and is similar to the induction and consolidation phases. The addition of a delayed-intensification phase by the BFM group led to significant improvement in survival in all patients with childhood ALL. Subsequent trials in the United States and Europe confirmed the importance of post-induction intensification in the long-term survival of patients with ALL. Survival among patients with high-risk leukemia may be further improved by augmenting the post-induction intensification regimen.

Although the first successful treatment of CNS leukemia included 2,400 to 3,600 cGy cranial radiation, in the last 2 decades, several trials have demonstrated that CNS radiation may be reduced (to 1,200–1,800 cGy) or eliminated in children with low-risk B-cell ALL with a rapid early response to induction therapy. The Total Therapy Study XV suggested that prophylactic cranial irradiation could be eliminated for all children with ALL. Children at high risk for bone marrow and CNS relapse received intensified treatment, including additional doses of intrathecal chemotherapy. Reduction in cranial radiation is designed to reduce long-term endocrine and cognitive effects, as well as the risk of secondary malignancies. However, the use of intensified intrathecal therapy and high-dose methotrexate (MTX) are also associated with late cognitive side effects even when administered without radiation therapy. Radiation therapy was eliminated from management in all CNS negative children with precursor B-cell ALL in the United States. The optimal CNS prophylaxis for T-cell ALL is not yet clearly defined.

Unlike treatment paradigms for most malignancies, successful therapy for childhood ALL includes a protracted maintenance period. Although the components of maintenance therapy vary between cooperative group studies, attempts to reduce therapy to less than 24 months have never been successful. Most maintenance therapy consists of oral mercaptopurine, oral MTX, intravenous vincristine, oral corticosteroid pulses, and intrathecal therapy once every several months. The therapy is adjusted to maximize the dose within a range that maximizes the antileukemic effect and minimizes toxicity, including myelosuppression and immunosuppression. Many children on maintenance chemotherapy may return to school and normal daily activities.

### Infant Acute Lymphoblastic Leukemia

In the 1970s, the survival among children older than 1 year of age with ALL approached 50%, and fewer than 20% of children younger than 1 year survived. Currently, infants still have a higher incidence of relapse, death from toxicity, and long-term side effects when compared with older children. Studies with intensified therapy in infants younger than 6 months of age demonstrated an event-free survival of less than 10%, and infants older than 6 months had an event-free survival of 40%. Incremental improvement in survival was achieved by simultaneously intensifying chemotherapy and modifying such intensity to reduce treatment-related mortality. Bone marrow transplantation for infants in first remission has been a subject of study for several years. However, to date, bone marrow transplant has not significantly improved outcomes for these patients. Transplantation poses several problems, including the fact that total body radiation is associated with significant long-term side effects in young infants. Alternatively, intensified multiagent chemotherapy, combined with novel targeted therapy, is currently being evaluated, with the use of bone marrow transplantation reserved for the setting of a relapse or for very high-risk infants. Ongoing studies in this unique and challenging subset of children will help further define the role of transplantation and intensified chemotherapy.

## TREATMENT OF ACUTE MYELOGENOUS LEUKEMIA

### Principles of Therapy

Unlike treatment strategies in ALL, the event-free survival rate in childhood AML has reached a plateau at 60% despite aggressive intensification of therapy. Individualized treatment regimens have worked to improve survival rates significantly in children with acute promyelocytic leukemia, but have done little for other subsets of AML.

About 85% to 90% of children will obtain a complete remission with cytarabine and daunorubicin in combination with either etoposide or thioguanine. Attempts to improve remission induction rates and long-term survival by substituting idarubicin or mitoxantrone for daunorubicin or by increasing the dose of cytarabine have largely yielded comparable efficacy and occasionally greater toxicity. Alternative approaches currently under investigation include the introduction of a

monoclonal antibody directed against CD33 (a surface antigen expressed on most myeloid neoplasms), the use of proteasome inhibitors (bortezomib), as well as the use of the multi-kinase inhibitor sorafenib for children with FLT3-ITD-positive AML.

Intensive postremission therapies were developed using multiagent regimens cycled every 4 to 6 weeks. No randomized head-to-head comparisons have been made of the different regimens, but none have succeeded in improving long-term, event-free survival beyond 60%. Allogeneic stem cell transplantation (STC) has been extensively evaluated in childhood AML. Some studies nonrandomly assign transplantation to patients with high-risk features, such as monosomy 5 or 7, or who remain MRD positive after induction. Relapse-free survival is generally better in the children who undergo transplantation, but overall survival is comparable because of transplant-related mortality. Among children with t(8;21), t(9;11), t(15;17), and *inv16*, NPM1, and CEBPA, all favorable molecular features, STC is currently not recommended in first remission (reviewed in 52 studies).

### Acute Promyelocytic Leukemia

When treated with standard AML therapy, children with acute promyelocytic leukemia (APL) fared poorly. Recent regimens intensifying the anthracycline dose and incorporating all-trans retinoic acid (ATRA) early in induction, with mercaptopurine, MTX, and ATRA maintenance therapy led to 5-year survival rates exceeding 80% among children with APL. Early death secondary to coagulopathy, including both hemorrhage and thrombosis, remains a major concern. Because of the success of a recent clinical trial that treated adult patients with APL with retinoic acid and arsenic trioxide alone, the Children's Oncology Group is evaluating the efficacy of using these 2 agents without additional chemotherapy in children. Given the late toxicity of chemotherapy described in the following text, the possibility of avoiding chemotherapy while still maintaining high cure rates is most desirable; however, the late side effects of the combination of ATRA and arsenic are not yet known.

## CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia (CML) accounts for approximately 3% of childhood leukemias. In children and adults, CML is characterized by the presence of the Ph chromosome. In CML, *BCR-ABL* encodes a 210-kDa dysregulated tyrosine kinase, which is found in more than 90% of childhood and adult CML cases.

Chronic myelogenous leukemia in childhood typically produces leukocytosis, which is marked by the presence of myeloid progenitor cells at all levels of differentiation, and thrombocytosis. Hepatosplenomegaly is present in most children. Symptoms of fatigue, weight loss, bone pain, and low-grade fevers may be present for weeks to months. Most children are diagnosed in the chronic phase with cytogenetic evidence of disease with fewer than 5% blasts in the marrow. Blast crisis is reflective of more advanced disease and is indistinguishable from AML, with the exception of the presence of the Ph chromosome as well as significant splenomegaly.

Until recently, standard therapy for CML in children and adults included hydroxyurea, interferon, and low-dose cytarabine. Although clinical improvements in hematologic parameters were possible with these therapies, cytogenetic remission was uncommon. More recently, imatinib mesylate was developed as a specific inhibitor of the *BCR-ABL* tyrosine kinase. Results from recent clinical trials have rapidly established imatinib as the standard of care for CML. Approximately 60% of patients who are refractory to interferon achieved a major cytogenetic response with imatinib, with infrequent hematologic toxicities. Imatinib is reportedly most effective in patients with chronic-phase CML (76% major cytogenetic response rate reported) compared with the accelerated phase, or blast crisis. A recent phase III prospective trial of more than 1,000 patients conclusively demonstrated that imatinib is superior to interferon- $\alpha$  plus low-dose cytarabine in inducing cytogenetic disease remission and prolonging progression-free survival in adult patients with chronic-phase CML. The effectiveness of imatinib in children with CML in chronic phase was recently reported, with 98% of children achieving a complete hematologic response, 61% achieving a complete cytogenetic response, and 31% achieving a major molecular response at 1 year after initiation of therapy. For children with CML resistant to imatinib, tyrosine kinase inhibitors dasatinib or nilotinib are often effective. Studies are ongoing to assess the use of newer-generation tyrosine kinase inhibitors in children with imatinib-resistant CML.

Imatinib mesylate and the newer-generation tyrosine kinase inhibitors dramatically changed therapy for CML, but do not constitute a cure. The only proven curative strategy for children with CML is allogeneic SCT. Survival after SCT for CML was previously reported to be 70% to 80% with a matched-sibling donor and 40% to 60% when unrelated donors are used. It is likely, with improved supportive care leading to decreased treatment-related mortality, that survival outcomes are now even greater after SCT. Whereas previously SCT was first-line therapy for children with CML, current expert opinion recommends SCT only for children who become refractory to imatinib. In the current era of imatinib mesylate therapy, once-unattainable cytogenetic and molecular remissions are not only possible, but also expected. If newer generation tyrosine kinase inhibitors yield durable remissions for children with imatinib-resistant CML, recommendations for SCT may be delayed further. However, it is important to note the potential need for lifelong treatment and that response to tyrosine kinase inhibitors and control of disease is significantly affected by adherence to therapy.

## JUVENILE MYELOMONOCYTIC LEUKEMIA

Juvenile myelomonocytic leukemia (JMML) is a clonal disorder of early childhood, occurring at a median age of 1.8 years. Hallmarks of the disease at diagnosis include marked hepatosplenomegaly, peripheral blood monocyte count of more than  $1 \times 10^9/L$ , and myeloid precursors in the peripheral blood. Chronic infections, lymphadenopathy, rash (eczema, xanthomas,

café-au-lait spots), and failure to thrive are also common. Association of JMML with several genetic syndromes has been established, including NF1 and Noonan syndrome. Bone marrow aspiration will reveal hypercellularity with a predominance of all stages of granulocyte maturation and a blast count of less than 20%, which is similar to the findings in CML with 1 key exception—patients with JMML do not harbor the Ph chromosome. With the exception of proving that no Ph chromosome is present, bone marrow aspiration is not diagnostic in JMML, as it is in the acute leukemias. The diagnosis of JMML can be made from clinical history and peripheral blood findings, with corroboration from bone marrow findings.

Monosomy 7 can be identified in 25% of children with JMML; 65% will have a normal karyotype. Thirty-five percent of patients will have somatic mutations of *PTPN11*, the gene encoding SHP-2, a tyrosine kinase involved in hematopoietic cell development. *RAS* and *NF-1* mutations have each been identified in 25% of children, and mutations in *CBL* (E3 Ubiquitin ligase) have been identified in 17% of children. Mutations in *PTPN11*, *RAS*, *NF-1*, and *CBL* seem to be mutually exclusive in JMML. Each may independently activate signaling through the *RAS*/MAP kinase-signaling pathway, increasing sensitivity of cells to granulocyte monocyte colony stimulating factor (GM-CSF).

The natural history of JMML, if untreated, is death within a median of approximately 1 year. At an age older than 2 years, thrombocytopenia and high hemoglobin F at diagnosis are all predictors of more aggressive disease. The European Working Group of Myelodysplastic Syndrome in Childhood reported a 5-year event-free survival in approximately 50% of children with JMML transplanted from matched-related and matched-unrelated donors. Treatment failures were primarily a result of disease recurrence within the first year after transplant. The role of conventional chemotherapy in the pretransplant setting or in children without an appropriate donor is not clearly defined. Most European trials typically use mercaptopurine or no therapy, whereas the current Children's Oncology Group trials in the United States administer cytarabine, fludarabine, and retinoic acid. GM-CSF agonists and farnesyltransferase inhibitors are currently being studied, but their role is yet to be defined. Children with JMML and Noonan syndrome may undergo spontaneous resolution, and watchful waiting and close observation are the standard of care.

## MYELODYSPLASIA

Myelodysplastic syndromes (MDS) are clonal disorders of ineffective or abnormal hematopoiesis that often precede AML or aplastic anemia. The most common chromosomal abnormality associated with MDS in children is monosomy 7 (7q-), although monosomy 5 and trisomy 8 are reported as well. Myelodysplastic syndromes may occur spontaneously or after exposure to radiation, epipodophyllotoxin, or alkylators. Diagnosis of the disease is based on identification of dysplastic features in the bone marrow, as well as characteristic cytogenetic abnormalities. Further classification is based on the number of blasts present in the marrow and is used primarily to predict progression

to AML. Acute myelogenous leukemia after contracting MDS is typically more difficult to treat than de novo AML. Currently, the only available therapy for MDS includes supportive care and (SCT). Lenalidomide, a derivative of thalidomide, induces cytogenetic remissions in adults with MDS, and studies are needed to assess the efficacy of lenalidomide in children with MDS.

## MYELOPROLIFERATIVE DISEASES

Current WHO classification of childhood leukemias includes JMML (discussed previously) among the myeloproliferative diseases of childhood. In addition, essential thrombocytosis and polycythemia vera are also reported in children. Newborns with Down syndrome may develop a myeloproliferation syndrome called transient abnormal myelopoiesis, also known as transient myeloproliferative disease, with clinical features that are indistinguishable from AML, including leukocytosis, organomegaly, fevers, and cytopenias with circulating blasts. The blasts typically express megakaryocyte markers and have mutations in GATA1, a transcription factor that is essential for normal hematopoiesis. Although life-threatening complications may occur in a minority of children, most experience spontaneous remission within a few months. Approximately 25% will develop leukemia within 1 to 3 years, and whether transient abnormal myelopoiesis is a malignant disease or a true myeloproliferative syndrome is unclear.

## RELAPSED LEUKEMIAS AND STEM CELL TRANSPLANTATION

### Acute Lymphoblastic Leukemia

Despite development of successful therapies in childhood leukemias, 20% to 25% of children with ALL and 50% of children with AML will relapse after chemotherapy treatment. In fact, more children are diagnosed with relapsed leukemia than Hodgkin disease and pediatric sarcomas. In most children with relapsed leukemia, long-term, event-free survival is less than 50%, even with SCT.

Two reliable predictors of survival after relapse are the duration of the first remission (improved survival after a longer first remission) and phenotype (relapsed B-lineage leukemias are more curable than T-lineage leukemias). According to the BFM group, a very early relapse occurs after a first remission of less than 18 months; an early relapse occurs after a first remission greater than 18 months but less than 6 months after completion of therapy; and a late bone marrow relapse occurs after a first remission of more than 18 months and more than 6 months after completion of therapy. Many centers are recommending systemic chemotherapy without SCT for children with a late relapse.

The Children's Cancer Study Group (CCG) 1900 series of clinical trials were completed between 1997 and 2002, and 4,464 children were treated on ALL trials. Bone marrow relapse occurred in 539 children (12%), CNS relapse in 194 (4%), and testicular relapse in 56 (1.5%). The overall 3-year survival after marrow relapse was 28% and 60% for CNS and testicular

relapse, respectively. Remission reinduction after relapse is relatively good, but overall survival remains poor owing to a deficiency in effective therapies. Most studies comparing SCT to chemotherapy approaches demonstrate an advantage to SCT. However, these studies typically include a significant selection bias (based on donor availability and response to remission reinduction). In 2005, Gaynon published a telling summary of data from the CCG 1941 study. Of a total of 214 children with marrow relapse within 12 months of the completion of primary therapy, approximately 75% achieved second remission. Children who achieved a second remission and who had matched-sibling donors were nonrandomly assigned to receive SCT. The remaining children were randomized to either an alternative donor (unrelated donor or mismatched related donor) transplant or continued chemotherapy. The disease-free survival at 3 years for the children receiving a matched sibling transplant and an unrelated donor transplant are approximately 50%. The 3-year event-free survival for children with a first remission less than 18 months is 4%, 18 to 30 months is 10%, and longer than 30 months is 41%. Most events occur within 6 months of relapse, and less than one-half of the children assigned to unrelated-donor transplants actually made it to transplant in second remission. These results are striking and speak strongly to the need for additional therapies for children with relapsed ALL.

Novel, targeted immunotherapy is currently being evaluated in children with relapsed and refractory ALL. Chimeric antigen receptor-modified T cells are T cells that are engineered to bind tumor cells via specific cell surface antigens, activate T cells upon binding, and induce cell death in the tumor cell. A recent case series in the *New England Journal of Medicine* reported that the CTL019 chimeric antigen receptor-modified T cells, which bind with specificity to common B ALL surface antigen CD19, induced a complete remission in 2 children with very high-risk, relapsed, or refractory ALL. The study showed significant expansion of the effector CTL019 cells in both children, and the engineered T cells were detected in the cerebrospinal fluid, a site where leukemia cells often escape the cytotoxic effects of systemic chemotherapy because of the blood-brain barrier. There is great promise for using chimeric antigen receptor-modified T cells to treat children with ALL not just in the relapsed or refractory setting, but also in children with newly diagnosed leukemia. However, large-scale studies are needed to further assess the safety and efficacy of this treatment modality.

### Acute Myelogenous Leukemia

As is the case with ALL, hematologic relapse remains the most common adverse event in children with AML. Approximately 30% to 40% of children who achieve a remission will relapse, and 25% will have residual disease after intensive induction therapy. Children with AML with high-risk features, such as monosomy 5 or 7 or persistent MRD, often undergo SCT in first remission; nevertheless, as many as 40% to 50% still relapse, and their relapse therapy may be severely limited or complicated by post-transplant toxicities. Remission reinduction rates for all children

with AML in first relapse ranges from 50% to 80% using multiagent chemotherapy. Overall survival after relapses is a dismal 30% to 40%. Although in ALL, a subset of children who relapsed late may still be salvaged with conventional chemotherapy, the only curative alternative for patients with relapsed AML remains SCT.

## PHARMACOGENETICS

Pharmacogenetics is the study of genetic differences in sensitivity of individuals to certain drugs. Genetic polymorphisms in specific genes that are responsible for regulating drug metabolism, transport, and target expression can have a profound effect on both therapeutic and toxic responses to leukemia therapies. Understanding the incidence and implications of polymorphisms affecting drug metabolism and distribution will ultimately help control individual variability in leukemia treatment protocols, with the goal of further reducing toxicity while maximizing efficacy.

### Thiopurine Metabolism

Thiopurine methyltransferase (TPMT) is a key enzyme in the metabolism of azathioprine, 6-mercaptopurine, and thioguanine. One in 300 individuals will have 2 alleles with TPMT polymorphisms, resulting in very low TPMT enzyme activity. Ten percent of individuals will have intermediate enzyme activity, resulting from 1 abnormal allele. Nearly 90% of the population is wild-type and defined as having normal enzyme activity. All patients with low activity, 35% with intermediate activity, and 7% with wild-type activity require 6-MP dose reductions. In terms of survival, not only are higher doses of 6-MP associated with improved outcomes, but defective TPMT metabolism is also associated with a higher incidence of topoisomerase II inhibitor-induced secondary AML and a higher risk of brain tumors in patients who receive concomitant radiation therapy. Commercially available genotype and phenotype analysis of the TPMT enzyme helps guide current thiopurine therapy, but it is still an evolving science and the results need to be interpreted with caution.

### Antifolate Metabolism

Ever since Sidney Farber gave aminopterin to a patient with childhood leukemia, antifolates (MTX eventually replaced aminopterin) have remained essential in the treatment of ALL. Polymorphisms in MTX transport, metabolism, and target expression may all affect leukemia cell sensitivity to MTX and illustrate how multiple polymorphisms may alter efficacy and toxicity of a single drug. The reduced folate carrier (RFC) is an active transport system for MTX. A decrease in RFC expression will lead to a decrease in the amount of MTX that accumulates intracellularly. Though not yet correlated to RFC function, specific RFC polymorphisms are associated with worse outcomes with standard therapy for ALL. MTX is a tight-binding inhibitor of dihydrofolate reductase, and the concentration of MTX required to achieve inhibition of enzyme activity increases in direct proportion to the amount of the enzyme in the target cells. Amplification of the

dihydrofolate reductase gene is seen in 30% of children with relapsed ALL, but only 10% of children with newly diagnosed ALL. Also implicated in survival in pediatric ALL are polymorphisms in other enzymes involved in MTX metabolism, including methylenetetrahydrofolate reductase (an enzyme responsible for the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate) and thymidylate synthase (a target of MTX).

In addition to the enzymes specifically involved in metabolism of MTX and thiopurines, several detoxifying enzyme systems have profound effects on a broader range of chemotherapeutic agents. The cytochrome P450 enzymes are involved in the activation or inactivation of a variety of anticancer agents. Polymorphisms in the cytochrome system have been implicated both in treatment efficacy and in toxicities, including vincristine neuropathies and treatment-related leukemias. Deletions in NR3C1 and BTG1 are associated with leukemia cell resistance to corticosteroids, and are found in a higher percentage of bone marrow samples obtained at the time of relapse compared to initial diagnosis. In addition, the pharmacokinetic interactions between chemotherapeutic agents are actively being uncovered. For example, higher exposure to asparaginase is associated with decreased clearance of dexamethasone, and thus increased leukemia cell exposure to corticosteroids. The combination of higher serum concentrations of both asparaginase and dexamethasone is associated with improved survival.

## LATE EFFECTS OF THERAPY

The successful treatment of childhood leukemias has come with a significant price. Nonetheless, the leukemias represent one of the most curable and common malignancies in childhood, and the number of survivors of childhood leukemia is ever increasing. The long-term side effects of treatment need to be monitored, anticipated, and treated effectively.

### Cognitive Function

Changes in cognitive function after cranial radiation are among the most well-studied side effects of leukemia therapy. Radiation-induced white-matter changes may result in deficits in speed of information processing, potentially progressive decrements in IQ testing, and poor school performance. Age at the time of treatment and total dose of radiation administered are the most reliable predictors of late cognitive effects. Patients receiving cranial radiation who are younger than 5 years of age, and especially younger than 3 years of age, are more susceptible to resultant cognitive deficiencies. Other significant observations include a dose-dependent effect between cognitive deficiencies after 1,800, 2,400, and 3,600 cGy cranial radiation. Accordingly, many recent treatment regimens attempt to eliminate cranial radiation for patients at lowest risk for CNS recurrence and to reduce the dose of radiation to 1,200 or 1,800 cGy for patients at highest risk for CNS recurrence. Pui and colleagues recently reported that cranial irradiation can potentially be eliminated for all patients with ALL while maintaining high cure rates. Intensifying intrathecal

therapy has proven to be effective prophylaxis against CNS recurrence while maintaining baseline long-term cognitive function; however, the late side effects of intensified intrathecal chemotherapy are not yet understood.

### Cardiac Effects

Anthracyclines will likely remain a crucial component of effective therapy for ALL and AML. The incidence and severity of cardiac toxicity relates to the cumulative dose of anthracycline; concomitant use of mediastinal radiation, cyclophosphamide, or ifosfamide; and younger age at diagnosis. Most current treatment regimens in childhood cancer are capped at a total cumulative anthracycline dose of 350 to 400 mg/m<sup>2</sup> to reduce late cardiac toxicities. Most ALL treatment regimens do not approach this level; however, increased risk of cardiotoxicity is seen at doses as low as 100 to 150 mg/m<sup>2</sup>. Polymorphisms in the CBR3 are associated with increased risk of cardiotoxicity with low doses of anthracyclines. In addition to cumulative doses, female gender and young age at diagnosis are also associated with a higher risk of late cardiac toxicities. Cardiac toxicities usually affect function, and may be asymptomatic until years after completion of therapy, usually exhibiting at times requiring rapid increases in cardiac output (eg, puberty, pregnancy, weight training). After a median of 450 mg/m<sup>2</sup> of anthracycline, a reported 23% of children have echocardiographic abnormalities 7 years after treatment. Children receiving high cumulative doses of anthracycline should maintain diligent follow-up, especially if echocardiographic abnormalities are detected before completion of therapy. The Children's Oncology Group recommends the frequency of cardiac monitoring with echocardiogram and electrocardiogram be based on the dose of anthracyclines administered and the child age at the time of treatment.

### Endocrine Effects

Craniospinal radiation may reduce adult standing height, resulting from both deficient growth of the vertebral bodies after spinal radiation and growth hormone deficiency after cranial radiation. Reduction in the dose of cranial radiation has reduced the incidence of growth hormone deficiency in survivors of childhood leukemia. For some children, growth hormone supplementation may be necessary and effective. Referral for an endocrine evaluation should be considered for all survivors of childhood leukemia with short stature or early puberty. Poor bone health, including osteoporosis and osteonecrosis, after corticosteroid administration is another significant problem that may affect growth and cause physical impairment.

Infertility is a rare side effect of ALL therapy and can occur secondary to chemotherapy (especially with alkylator-based regimens) and radiation (especially in boys who required testicular radiation). Abnormal gonadal development and function may result from direct damage to the gonads after radiation or to the hypothalamic-pituitary axis after cranial radiation. In a study of 60 survivors of ALL, Sklar and colleagues identified significant germ cell dysfunction (increased

follicle-stimulating hormone and reduced testicular volume) in 55% of children treated with testicular radiation and 17% of children treated with craniospinal radiation. Leydig cell function was relatively preserved. Total alkylator dose and age at diagnosis are other predictors of fertility after treatment.

### Second Malignant Neoplasms

The risk and development of a second malignancy is a devastating side effect of both chemotherapy and radiation therapy for childhood ALL, although the risk is significantly less than that reported for other childhood malignancies. The cumulative incidence of any second neoplasm in survivors of childhood leukemia is reportedly 1.18% at 10 years (95% confidence interval is 0.8%–1.5%), which is a 7.2-fold increased risk above the general population, and the 25-year cumulative incidence is 5.2%. Cranial radiation, relapse, and female gender have all been associated with an increased risk for developing a second malignancy. Secondary leukemias and myelodysplasia, soft-tissue sarcomas, brain tumors, and solid tumors are all reported, although secondary CNS malignancies are the most common in children who received cranial spinal radiation. Deficiencies in TPMT may predispose children to secondary brain tumors. In a protocol incorporating high doses of antimetabolites, the 8-year cumulative incidence of secondary brain tumors among TPMT-deficient children was 43%. Children with normal TPMP activity had an 8-year cumulative incidence of secondary brain tumors of 8.3%. This exceptionally high incidence of secondary brain tumors in both groups likely reflects the concomitant use of cranial radiation and high-dose antimetabolites.

Identification of the possible late side effects of leukemia therapy has been key in the development of risk-stratified therapy. Reducing cumulative doses of agents with significant short- and long-term side effects while maintaining excellent cure rates in children with ALL is one of the great triumphs of oncology clinical trials. As more is learned, future therapies may take into account not only the biological features of the leukemia that are predictive of chemoresponsiveness, but also the host factors that determine risk for acute and long-term toxicities.

### CONCLUSIONS

Treatment of childhood leukemias is widely touted as a great success in oncology clinical trials, largely because of the continued incremental increases in long-term survival in children with ALL. Significant challenges still lay ahead as we define new strategies for treating AML and relapsed leukemias, as well as the myeloproliferative and myelodysplastic disorders. Application of risk-adapted therapy to patients with ALL and AML has allowed for continued improvement in long-term event-free survival and a reduction in long-term side effects. What has been learned about leukemia biology, host pharmacogenetics, and environmental influences on leukemia development has led to the development of effective treatment for childhood leukemias. The next frontier in cancer therapy in general, and leukemia therapy specifically, is targeted treatment plans based on leukemia cell and host

genetics. Imatinib mesylate and FLT3–targeted therapies are early examples of such approaches, but there is still a significant amount of work to be done to apply genomics to all leukemias in all children.

## Chapter 286 LIPID ABNORMALITIES

Jorge A. Alvarez, MD, PhD; Tracie L. Miller, MD;  
Sarah E. Messiah, PhD, MPH; Steven E. Lipshultz, MD

A pediatrician must consider multiple factors when assessing a child's global risk for premature cardiovascular disease. Other chapters in this text cover

general aspects of screening, the physical examination, and specific diagnoses, such as hypertension (see Chapter 163, High Blood Pressure), heart failure (see Chapter 361, Heart Failure), and congenital and acquired heart disease (see Chapter 234, Congenital and Acquired Heart Disease). This chapter describes 3 major topics that should be routinely addressed when assessing children and adolescents for the risks of cardiovascular disease, especially those with lipid abnormalities: (1) atherosclerosis, (2) obesity, and (3) smoking with a focus on atherosclerosis. The behavioral recommendations to patients and families, screening tests, and practice guidelines needed to provide care are summarized to serve as a quick reference for any preventive care consultation.

### ATHEROSCLEROSIS

Atherosclerosis continues to be a leading cause of death and disability in the United States. Although myocardial infarction, stroke, and other manifestations of atherosclerosis usually occur in adults, evidence is mounting that pathogenesis begins much earlier. Furthermore, overwhelming epidemiologic evidence has established that atherosclerosis is not an inevitable consequence of aging but rather, in many cases, an acquired disease with well-described risk factors that begins in childhood. Many risk factors for heart disease are beyond the control of the individual; some, such as hyperlipidemia and level of physical activity, can be modified; and at least one factor—smoking—is completely avoidable. A goal of pediatric primary care is to prevent the development of cardiovascular risk factors and the associated cardiovascular diseases to reduce their morbidity and mortality. Several risk factors for coronary heart disease are now easily identified during childhood, and evidence-based recommendations to begin prevention in childhood have been developed. Because the process of atherosclerosis and the habits that influence the risk for heart disease begin early in life, preventive measures should be initiated during childhood (see Table 286-1).

The known risk factors for atherosclerosis include hypertension, smoking, elevated low-density lipoprotein cholesterol (LDL-C), decreased high-density lipoprotein cholesterol (HDL-C), diabetes mellitus, advancing age, male sex, a family history of premature heart disease, hypertriglyceridemia, sedentary lifestyle, and obesity. Primary prevention in childhood should seek to eliminate or minimize these risk factors. A relatively new concept, “primordial prevention,” also challenges health care providers to address the social and environmental conditions that create and maintain the risk factors themselves. Changing these systemic conditions is particularly important in controlling obesity, smoking, and sedentary lifestyles.

A classic study by Enos, Beyer, and Holmes of military personnel killed in the Korean War illustrates the importance of early influence of environmental factors. The study revealed that young American soldiers had a 77% incidence of coronary arterial lesions, whereas such lesions were virtually nonexistent among young Korean soldiers. This study not only described the early beginnings of the atherosclerotic

## Table 286-1

		AGE				
RISK FACTOR	BIRTH TO 12 MO	1-4 Y	5-9 Y	9-11 Y	12-17 Y	18-21 Y
		At 3 y, evaluate family history for early CVD: parents, grandparents, aunts/uncles, men $\leq 55$ y old, women $\leq 65$ y old; review with parents and refer as needed; positive family history identifies children for intensive CVD RF attention	Update at each nonurgent health encounter	Reevaluate family history for early CVD in parents, grandparents, aunts/uncles, men $\leq 55$ y old, women $\leq 65$ y old	Update at each nonurgent health encounter	Repeat family-history evaluation with patient
Tobacco exposure	Advise smoke-free home; offer smoking-cessation assistance or referral to parents	Continue active antismoking advice with parents; offer smoking-cessation assistance and referral as needed	Obtain smoke exposure history from child Begin active antismoking advice with child	Assess smoking status of child; active antismoking counseling or referral as needed	Continue active antismoking counseling with patient; offer smoking-cessation assistance or referral as needed	Reinforce strong antismoking message; offer smoking-cessation assistance or referral as needed
Nutrition/diet	Support breastfeeding as optimal to 12 mo of age if possible; add formula if breastfeeding decreases or stops before 12 mo of age	At age 12-24 mo, may change to cow's milk with 2% percentage of fat decided by family and pediatric care provider; after 2 y of age, fat-free milk for all; juice $\leq 4$ oz/d; transition to CHILD-1 diet by the age of 2 y	Reinforce CHILD-1 diet messages	Reinforce CHILD-1 diet messages as needed	Obtain diet information from child and use to reinforce healthy diet and limitations and provide counseling as needed	Review healthy diet with patient
Growth, overweight/obesity	Review family history for obesity; discuss weight-for-height tracking, growth chart, and healthy diet	Chart height/weight/BMI; classify weight-by BMI from age 2 y; review with parent	Chart height/weight/BMI and review with parent; BMI $\geq 85$ th percentile, crossing percentiles: Intensify diet/activity focus for 6 mo; if no change: RD referral, manage per obesity algorithms <sup>a</sup>	Chart height/weight/BMI and review with parent and child; BMI $\geq 85$ th percentile, crossing percentiles: Intensify diet/activity focus for 6 mo; if no change: RD referral, manage per obesity algorithms <sup>a</sup>	Chart height/weight/BMI and review with child and parent; BMI $\geq 85$ th percentile, crossing percentiles: intensify diet/activity focus for 6 mo; if no change: RD referral, manage per obesity algorithms <sup>a</sup>	Review height/weight/BMI and norms for health with patient; BMI $\geq 85$ th percentile, crossing percentiles: intensify diet/activity focus for 6 mo; if no change: RD referral, manage per obesity algorithms <sup>a</sup>

		AGE				
RISK FACTOR	BIRTH TO 12 MO					
		1-4 Y	5-9 Y	9-11 Y	12-17 Y	18-21 Y
Lipids	No routine lipid screening	Obtain FLP only if family history for CVD is positive, parent has dyslipidemia, child has any other RFs or high-risk condition	Obtain FLP only if family history for CVD is positive, parent has dyslipidemia, child has any other RFs or high-risk condition	Obtain universal lipid screen with nonfasting non-HDL = TC – HDL, or FLP: manage per lipid algorithms <sup>a</sup> as needed	Obtain FLP if family history newly positive, parent has dyslipidemia, child has any other RFs or high-risk condition; manage per lipid algorithms <sup>a</sup> as needed	Measure 1 nonfasting non-HDL or FLP in all: review with patient; manage with lipid algorithms <sup>a</sup> per ATP as needed
BP	Measure BP in infants with renal/urologic/cardiac diagnosis or history of neonatal ICU	Measure BP annually from the age of 3 y; chart for age/gender/height percentile and review with parent	Check BP annually and chart for age/gender/height: review with parent; workup and/or management per BP algorithm <sup>a</sup> as needed	Check BP annually and chart for age/gender/height: review with parent; workup and/or management per BP algorithm <sup>a</sup> as needed	Check BP annually and chart for age/gender/height: review with adolescent and parent; workup and/or management per BP algorithm <sup>a</sup> as needed	Measure BP: review with patient; evaluate and treat per JNC guidelines <sup>a</sup>
Physical activity	Encourage parents to model routine activity; no screen time before the age of 2 y	Encourage active play; limit sedentary/screen time to ≤2 h/d; no TV in bedroom	Recommend MVPA of ≥1 h/d; limit screen/sedentary time to ≤2 h/d	Obtain activity history from child: recommend MVPA of ≥1 h/d and screen/sedentary time of ≤2 h/d	Use activity history with adolescent to reinforce MVPA of ≥1 h/d and leisure screen time of ≤2 h/d	Discuss lifelong activity, sedentary time limits with patient
Diabetes	—	—	—	Measure fasting glucose level per ADA guidelines <sup>a</sup> refer to endocrinologist as needed	Measure fasting glucose level per ADA guidelines <sup>a</sup> refer to endocrinologist as needed	Obtain fasting glucose level if indicated; refer to endocrinologist as needed

ADA, American Diabetes Association; ATP, Adult Treatment Panel III ("Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults"); JNC, Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; MVPA, moderate-to-vigorous physical activity; RD, registered dietitian; RF, risk factor

<sup>a</sup>All algorithms and guidelines mentioned in this schedule are included in the summary report. The full and summary reports of the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents can also be found on the National Heart, Lung, and Blood Institute Web site ([www.nhlbi.nih.gov](http://www.nhlbi.nih.gov)). From Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents: summary report. *Pediatrics*. 2011;128(suppl 5):S213–S256. Available at: [pediatrics.aappublications.org/content/128/Supplement\\_5/S213](http://pediatrics.aappublications.org/content/128/Supplement_5/S213).

process but also suggested the importance of dietary and lifestyle modifiers in its development. Similarly, the Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study group showed that risk factors, such as cholesterol levels and smoking, contribute to the formation of atherosclerosis in a graded manner and that these factors are present in children and young adults long before the onset of clinical heart disease. In addition, several large studies, including the Bogalusa, Louisiana study and others in Australia and Finland, using carotid intima media thickness as a noninvasive measure of atherosclerosis, have established that dyslipidemia in childhood correlates with dyslipidemia in adulthood.

Hypercholesterolemia is a primary target for preventing atherosclerosis. Total cholesterol measures the cholesterol contained in several lipid particles, including LDL-C, HDL-C, and very-low-density lipoprotein cholesterol (VLDL-C). Whereas LDL-C is one of the atherogenic lipoproteins and receives the focus for screening algorithms, HDL-C protects against the development of coronary heart disease.

Both genetic and environmental factors are important in the development of hypercholesterolemia. Plasma cholesterol levels are influenced by the quantity and quality of dietary fat intake and by the individual's ability to synthesize and degrade cholesterol. Severe or familial hypercholesterolemia secondary to a defect in the LDL receptor occurs in approximately 1 in 500 individuals. Children with this inherited defect commonly have LDL-C values between 200 and 300 mg/dL, which is 2 to 3 times higher than the acceptable limits of normal (see Table 286-2). These children have a strong predilection for atherosclerotic heart disease as young adults. More than 600 different mutations of the LDL receptor have been described. Approximately 50% of men who have one of these mutations will have a myocardial infarction by age 50 years, and between 75% and 85% will have a myocardial infarction by age 60 years. Approximately 50% of women will develop ischemic heart disease by age 60 years. Fortunately, even in these high-risk patients, treatment can decrease the incidence of heart disease.

In 1991, the National Cholesterol Education Program (NCEP) issued guidelines for preventing heart disease in children. In 1998, the American Academy of Pediatrics (AAP) published a revised statement that

included additional scientific justifications for emphasizing cholesterol screening and treatment. In 2002, the American Heart Association (AHA) issued a scientific statement supporting the NCEP's guidelines for both screening and treatment strategies that included a comprehensive and easy-to-follow review of other key areas in preventive cardiology. In 2008, the AAP revised its policy statement, which emphasizes screening overweight children and that proposes a lower age for pharmacologic treatment. The National Heart, Lung, and Blood Institute (NHLBI) created an Expert Panel to perform a systematic review of the evidence and issue new comprehensive guidelines for cardiovascular health, which were published in 2011 and endorsed by the AAP. The most recent adult guidelines, which transitioned ownership from the NHLBI's NCEP to the AHA and American College of Cardiology, limit their conclusion to those aged 21 years or older. Readers interested in an in-depth evaluation of the pertinent topics in preventive cardiology are referred to the NHLBI Expert Panel summary report.

### Recommendations for Cholesterol Screening

The 2007 report by the United States Preventive Services Task Force, despite good evidence for dyslipidemia tracking from childhood into adulthood, concluded that this evidence was insufficient to recommend for or against screening of lipid disorders in children and adolescents. The NHLBI Expert Panel suggests 2 separate approaches to hypercholesterolemia screening in children: a broad, population-based approach, and an individualized patient approach. The NHLBI Expert Panel was concerned that 30% to 60% of dyslipidemic children are missed, and has issued a significant change to screening, as discussed in the next section.

### Population Screening and Prevention

The NHLBI Expert Panel recommends universal screening at one time between the ages of 9 and 11 years and again between ages 17 and 21 years with either a random non-HDL cholesterol level (total cholesterol minus HDL-C) or a fasting LDL-C. For the remainder of children, the panel suggests that all children older than 2 years of age follow the CHILD-1 Diet, which is relatively low in fat: no more than 30% of total calories should come from fat, less than 10% of total calories should come from saturated

**Table 286-2**

**Classification of Total and Low-Density Lipoprotein Cholesterol Levels in Children and Adolescents From Families With Hypercholesterolemia or Premature Cardiovascular Disease**

CATEGORY	TOTAL CHOLESTEROL (MG/DL)	LOW-DENSITY LIPOPROTEIN CHOLESTEROL (MG/DL)
Acceptable	<170	<110
Borderline	170–199	110–129
High	≥200	≥130

From American Academy of Pediatrics. National Cholesterol Education Program. Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. *Pediatrics*. 1992;89(3 Pt 2):525–584.

fat, and total cholesterol consumption should be less than 300 mg per day. This diet should contain a variety of foods and should be adequate to support growth and maintain an ideal body weight for height and age. In 2009, a consensus statement issued by the AHA and endorsed by the AAP contained more detailed dietary recommendations for all children (see Box 286-1, Box 286-2). Overall, the population approach attempts to “shift the distribution” and reduce exposure throughout the population, the hallmark activity of public health, with pediatricians being a vital part of this reduction (see Table 286-3).

### Individualized Screening

In addition to population-wide screening and dietary recommendations, the guidelines suggest risk assessment and cholesterol testing in children older than 2 years of age with a family history of atherosclerotic disease, that is, whose parent or grandparent has or had premature coronary heart disease, defined as onset of disease before age 56 years. Conditions suggesting heart disease in families include documented myocardial infarction, angina pectoris, peripheral vascular disease, cerebrovascular disease, or sudden cardiac death, as well as coronary atherosclerosis as determined by angiography or by a history of balloon angioplasty or coronary artery bypass graft surgery. In addition, children who have a parent with hypercholesterolemia (total cholesterol  $\geq 240$  mg/dL) also should be screened. Children whose parental history is unknown or unobtainable, especially if they have other risk factors, may also be screened to identify those in

need of nutritional advice. Parents with unknown cholesterol levels should be encouraged to obtain a full lipoprotein analysis (a lipid profile). Cholesterol levels may also need to be determined for children at higher risk for coronary heart disease independent of family history (eg, children who smoke, are obese, have diets rich in saturated fats and cholesterol, or have diabetes mellitus). For children with a family history of premature heart disease and with personal risk factors listed above, the guidelines suggest obtaining a fasting lipid profile that includes total cholesterol, LDL-C, HDL-C, and triglycerides once between 2 and 8 years of age and again between 12 and 16 years of age if the initial screening is normal and the child is not already under treatment, or if any risk factors are newly discovered or present at time of subsequent clinical encounter.

The NHLBI Expert Panel endorsed a risk stratification and treatment algorithm for children at increased risk for premature coronary heart disease. Children needing special consideration for cardiovascular risk factors are those with homozygous or heterozygous familial hypercholesterolemia, diabetes mellitus (type 1 or 2), chronic kidney disease or end-stage renal disease, Kawasaki disease, congenital heart disease, and chronic inflammatory disease, and survivors of transplant surgery or cancer treatment. Children with these

#### BOX 286-1 American Heart Association Recommended Pediatric Dietary Strategies for Parents and Families With Children Older Than 2 Years

- Balance caloric intake with physical activity to maintain normal growth.
- Engage in 60 minutes of moderate to vigorous play or physical activity daily.
- Eat vegetables and fruits daily and limit juice intake.
- Use vegetable oils and soft margarines low in saturated fat and trans fatty acids instead of butter or most other animal fats in the diet.
- Eat whole-grain breads and cereals rather than refined grain products.
- Reduce the intake of sugar-sweetened beverages and foods.
- Use nonfat (skim) or low-fat milk and dairy products daily.
- Eat more fish, especially oily fish, broiled or baked.
- Reduce salt intake, including salt from processed foods.

From Gidding SS, Lichtenstein AH, Faith MS, et al. Implementing American Heart Association Pediatric and Adult Nutrition Guidelines. *Circulation*. 2009;119:1161–1175. © American Heart Association, Inc. Reprinted with permission.

#### BOX 286-2 Tips for Parents to Implement the American Heart Association Pediatric Dietary Guidelines

- Reduce added sugars, including sugar-sweetened drinks and juices.
- Use canola, soybean, corn, safflower, or other unsaturated oils in place of solid fats when preparing food.
- Use the recommended portion sizes given on food labels when preparing and serving food.
- Use fresh, frozen, and canned vegetables and fruits and serve at every meal; be careful with added sauces and sugar.
- Introduce and regularly serve fish as an entrée.
- Remove the skin from poultry before eating.
- Use only lean cuts of meat and reduced-fat meat products.
- Limit high-calorie sauces such as Alfredo, cream sauces, cheese sauces, and Hollandaise.
- Eat whole-grain breads and cereals rather than refined produces; read the labels to ensure that *whole grain* is the first ingredient on the food label of these products.
- Eat more legumes (beans) and tofu in place of meat for some entrées.
- Breads, breakfast cereals, and prepared food, including soups, may be undesirably high in salt or sugar or both; read food labels for content, and choose high-fiber, low-salt, low-sugar alternatives.

From Gidding SS, Lichtenstein AH, Faith MS, et al. Implementing American Heart Association Pediatric and Adult Nutrition Guidelines. *Circulation*. 2009;119:1161–1175. © American Heart Association, Inc. Reprinted with permission.

**Table 286-3** Cardiovascular Health Integrated Lifestyle Diet (CHILD) Macronutrient Recommendations for Age 12 Months or Older

NUTRIENT	CHILD-1	CHILD-2
Calories	Adequate for normal growth	
Total fat	≤30% of calories	Same
Saturated fat	<10% of calories	≤7%
Polyunsaturated fat	Up to 10% of calories	Same
Monounsaturated fat	Remainder of fat calories	Same
Carbohydrates	Approximately 55% of calories	Same
Protein	Approximately 15%–20% of calories	Same
Cholesterol (mg/day)	<300	<200

**Table 286-4** Classification of Children at High Risk for Cardiovascular Disease: Condition-Specific Treatment Recommendations

RISK	RATIONALE	DISEASE PROCESS OR CONDITION
Tier I: high risk	Manifest coronary artery disease before age 30 years; clinical evidence	<ul style="list-style-type: none"> <li>• Homozygous familial hypercholesterolemia</li> <li>• Diabetes mellitus, type 1</li> <li>• Chronic kidney disease or end-stage renal disease</li> <li>• Postorthotopic heart transplantation</li> <li>• Kawasaki disease with current coronary aneurysms</li> </ul>
Tier II: moderate risk	Accelerated atherosclerosis: pathophysiologic evidence	<ul style="list-style-type: none"> <li>• Heterozygous familial hypercholesterolemia</li> <li>• Kawasaki disease with regressed coronary aneurysms</li> <li>• Diabetes mellitus, type 2</li> <li>• Chronic inflammatory disease</li> </ul>
Tier III: at risk	High-risk setting for accelerated atherosclerosis: epidemiologic evidence	<ul style="list-style-type: none"> <li>• Cancer treatment survivor</li> <li>• Congenital heart disease</li> <li>• Kawasaki disease without detected coronary involvement</li> </ul>

From Kavey R-EW, Allada V, Daniels SR, et al. Cardiovascular risk reduction in high-risk pediatric patients: a scientific statement from the American Heart Association Expert Panel on Population and Prevention Science; the Councils on Cardiovascular Disease in the Young, Epidemiology and Prevention, Nutrition, Physical Activity and Metabolism, High Blood Pressure Research, Cardiovascular Nursing, and the Kidney in Heart Disease; and the Interdisciplinary Working Group on Quality of Care and Outcomes Research: Endorsed by the American Academy of Pediatrics. *Circulation*. 2006;114(24):2710–2738. © American Heart Association, Inc. Reprinted with permission.

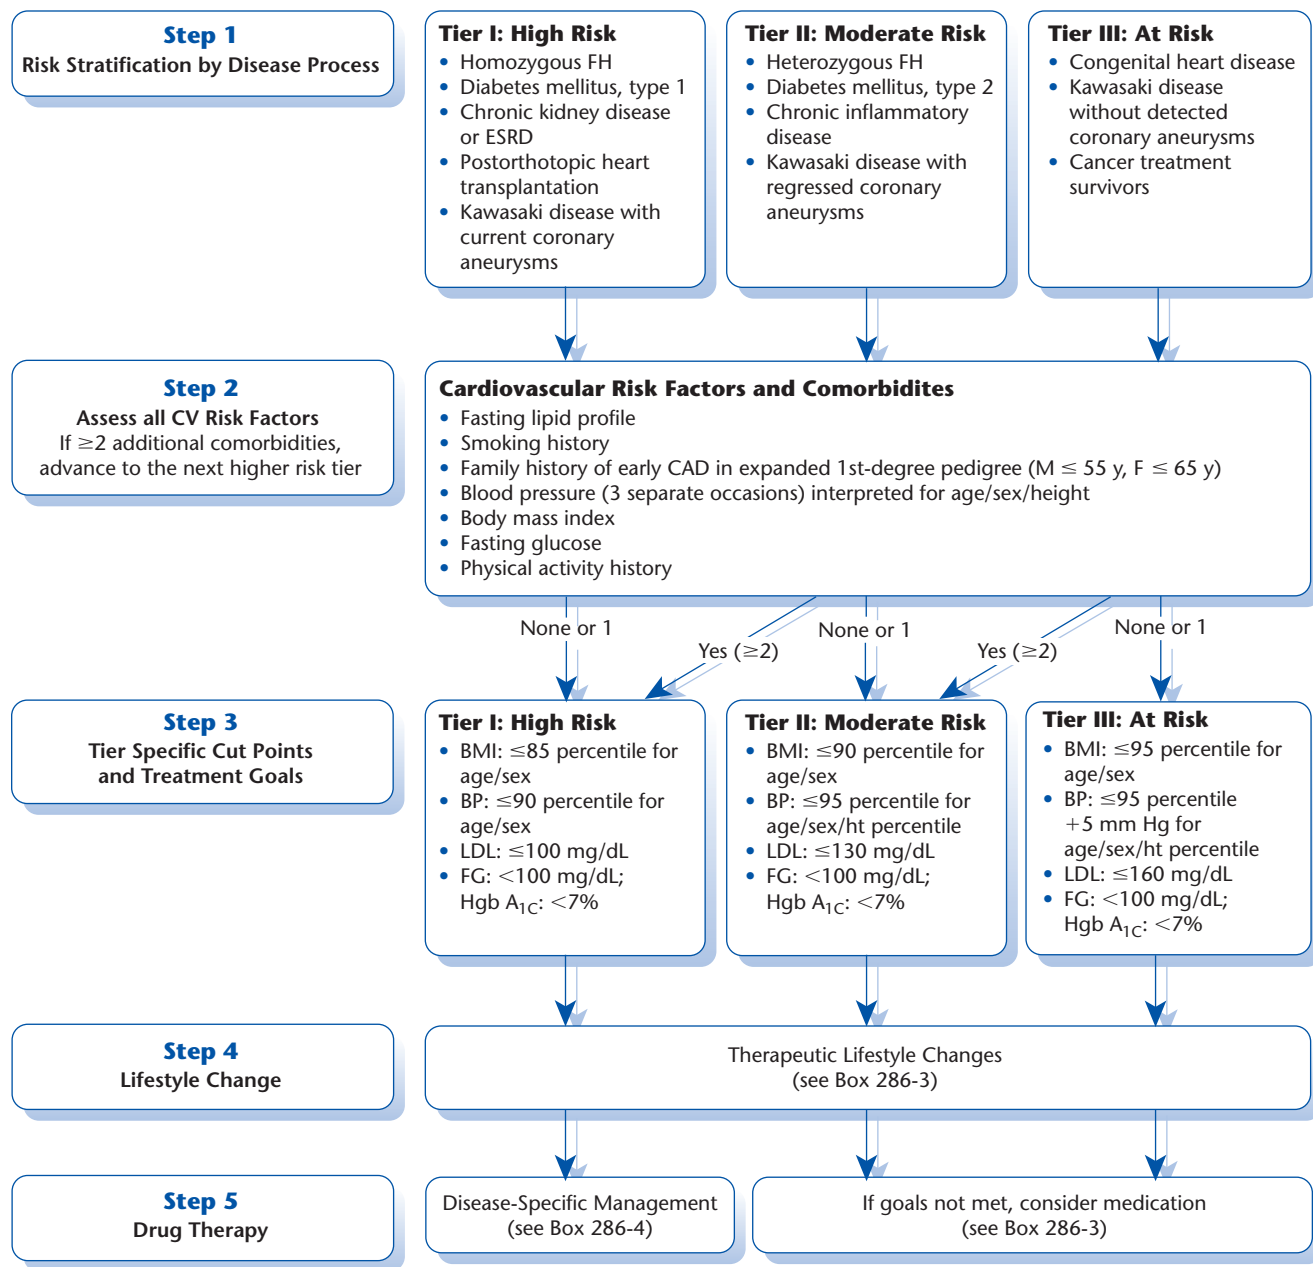

conditions are categorized into 3 tiers (see Table 286-4). An algorithm for screening with tier-specific cutoff values is provided (see Figure 286-1). Also included (see Box 286-3) are therapeutic goals for all tiers, as well as condition-specific recommendations for children in the highest tier, tier I (see Box 286-4).

### Recommendations for Treatment

Most of the information regarding the risk for heart disease in adults is based on fasting LDL-C values; therefore, recommendations for children are also based on fasting LDL-C values. Because cholesterol standards vary by age, treatment values are based on percentile ranks of children in the United States that exceed the upper norms. A total cholesterol level

greater than 200 mg/dL and an LDL-C level greater than 130 mg/dL represent values above the 95th percentile for children and are designated as high. A total cholesterol level less than 170 mg/dL and an LDL-C level less than 110 mg/dL represent values below the 75th percentile and are acceptable. Values between these limits are considered borderline (see Table 286-2).

All of these cutoff values were approved by consensus of the NCEP Expert Panel on Blood Cholesterol Levels in Children and Adolescents and are based on data published in 1980 from the Lipid Research Clinics Prevalence Study from children ranging from 1 to 19 years of age for total cholesterol and from 5 to 19 years of age for LDL-C. The NHLBI Expert Panel

**Figure 286-1** High-risk pediatric populations: risk stratification and treatment algorithm. Directions: Step 1: Risk stratification by disease process (see Table 286-4). Step 2: Assess all cardiovascular risk factors. If two or more comorbidities exist, then assign patient to the next higher risk tier for subsequent management. Step 3: Tier-specific intervention cut points or treatment goals defined. Step 4: Initial therapy: for tier I, initial management is therapeutic lifestyle change (see Box 286-3) plus disease-specific management (see Box 286-4). For tiers II and III, initial management is therapeutic lifestyle change (see Box 286-3). Step 5: for tiers II and III, if goals are not met after initial management, consider medication as outlined in Box 286-3.

BP, Blood pressure; CAD, coronary artery disease; CV, cardiovascular; ESRD, end-stage renal disease; FG, fasting glucose; FH, familial hypercholesterolemia; Hgb A<sub>1C</sub>, hemoglobin A<sub>1C</sub>; ht, height; LDL, low-density lipoprotein.

### BOX 286-3 Treatment Recommendations for Children at High Risk for Cardiovascular Disease, by Indication

#### GROWTH AND DIET

- Nutritionist evaluation, diet education for all (see Step 1 Diet recommendations in Table 286-3)
- Calculate body mass index (BMI) percentile for sex and height. Normal BMI values for age and sex are available at [www.cdc.gov/growthcharts](http://www.cdc.gov/growthcharts)
- If initial body mass index is >95th percentile:
  - Age-appropriate, reduced-calorie training for child and family
  - Specific diet and weight follow-up every 2 to 4 weeks for 6 months; repeat body mass index calculation at 6 months
  - Activity counseling (see ACTIVITY)
- If follow-up body mass index is >85th percentile for tier I, >90th percentile for tier II, or >95th percentile for tier III:
- Referral to weight-loss and exercise training programs appropriate for cardiac status

#### BLOOD PRESSURE (TIERS I, II, AND III)

- Blood pressure measurement or interpretation for age, sex, and height
  - If SBP or DBP is between the 90th and 95th percentiles or BP is >120/80 mm Hg (on 3 separate occasions within 1 month):
    - Recommend decreased calorie intake and increased activity for 6 months.
  - If initial SBP or DBP is >95th percentile (confirmed within 1 week) or 6-month follow-up or SBP or DBP is >95th percentile:
    - Initiate pharmacologic therapy per Fourth Task Force recommendations.

#### LIPIDS

- Low-density lipoprotein cholesterol, LDL-C (tiers II and III)
- See Box 286-4 for recommendations for LDL-C in tier I.
- If initial LDL-C is  $\geq 130$  mg/dL (tier II) or >160 mg/dL (tier III):
  - Nutritionist training for Step 2 Diet (see Table 286-3) along with avoiding trans fats for 6 months
- If repeat LDL-C is  $\geq 130$  mg/dL in tier II or >160 mg/dL in tier III and the child is older than 10 years:
  - Initiate statin therapy with LDL-C goal of 130 mg/dL.

#### TRIGLYCERIDES

- If initial triglyceride levels are between 150 and 400 mg/dL:
  - Nutritionist training for low-simple-carbohydrate, low-fat diet
  - If elevated triglycerides are associated with excess weight, nutritionist referral for weight loss

management: energy balance training plus activity recommendations (see ACTIVITY)

- If triglycerides are between 700 and 1,000 mg/dL, initial or follow-up:
  - Consider fibrate or niacin if >10 years of age. (Triglyceride levels  $\geq 1,000$  mg/dL are associated with substantial risk for acute pancreatitis. A fasting triglyceride of 700 mg/dL is likely to rise to >1,000 mg/dL postprandially. Treatment recommendations are congruent with those for managing dyslipidemia in diabetic children.
  - Weight loss is recommended when elevated triglycerides occur with overweight or obesity.

#### GLUCOSE (TIERS I, II, AND III, EXCEPT FOR PATIENTS WITH DIABETES MELLITUS)

- If fasting glucose is between 100 and 126 mg/dL:
  - Recommend reduced-calorie diet, increased activity aimed at 5% to 10% decrease in weight over 6 months.
- If repeat fasting glucose is between 100 and 126 mg/dL:
  - Recommend insulin-sensitizing medication as per endocrinologist.
- A casual glucose >200 mg/dL or a fasting glucose >126 mg/dL indicates diabetes mellitus. Refer to endocrinology for evaluation and management.
- Maintain hemoglobin HbA1c <7%.

#### SMOKING (TIERS I, II, AND III)

- Obtain parental smoking history at every visit; child smoking history beginning at age 10. Provide active antismoking counseling for all; smoke-free home strongly recommended at each encounter.
- Provide smoking cessation referral for any history of cigarette smoking.

#### ACTIVITY (TIERS I, II, AND III)

- For children in all tiers, participation in activity is at the discretion of the physician(s) directing care. For specific cardiac diagnoses, such as Kawasaki disease and congenital heart disease, activity guidelines are referenced in Box 286-4.
  - Obtain specific activity history for the child, focusing on time spent in active play and screen time (television + computer + video game times). Goal is  $\geq 1$  hour of active play per day; screen time limited to  $\leq 2$  hours/day.
- Encourage activity at every encounter.
  - After 6 months, if goals are not met, consider referral for exercise testing and recommendations from exercise specialist.

Specific treatment goals for each risk factor and each tier are given in the algorithm (see Figure 286-1).

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

From Kavey R-EW, Allada V, Daniels SR, et al. Cardiovascular risk reduction in high-risk pediatric patients: a scientific statement from the American Heart Association Expert Panel on Population and Prevention Science; the Councils on Cardiovascular Disease in the Young, Epidemiology and Prevention, Nutrition, Physical Activity and Metabolism, High Blood Pressure Research, Cardiovascular Nursing, and the Kidney in Heart Disease; and the Interdisciplinary Working Group on Quality of Care and Outcomes Research: endorsed by the American Academy of Pediatrics. *Circulation*. 2006;114(24):2710-2738. © American Heart Association, Inc. Reprinted with permission.

### BOX 286-4 High-Risk Stratification for Cardiovascular Disease: Treatment Recommendations for Tier-I Conditions

- Rigorous, age-appropriate education in diet, activity, and smoking cessation for all patients.
- Specific therapy as needed to achieve BP, LDL-C, glucose, and HbA1c goals as indicated for each tier outlined in the algorithm (Figure 286-1); timing should be individualized for each patient and diagnosis. Step 1 and step 2 therapy for all outlined in Box 286-3.

#### HOMOZYGOUS FAMILIAL HYPERCHOLESTEROLEMIA

- LDL management: scheduled apheresis every 1 to 2 weeks beginning at diagnosis to maximally lower LDL-C, plus statin and cholesterol absorption inhibitor.
- Prescription per cardiologist or lipid specialist. (Specific therapeutic goals for LDL-C are not meaningful with this diagnosis.)
- Assess body mass index, blood pressure, and fasting glucose: step 1 management for 6 months.
- If tier I goals are not achieved, proceed to step 2.

#### DIABETES MELLITUS, TYPE 1

- Intensive glucose management by endocrinologist, with frequent glucose monitoring or insulin titration to maintain plasma glucose levels <200 mg/dL and HbA1c <7%.
- Assess body mass index, BP, fasting lipids: step 1 management of weight, lipids for 6 months.
- If goals not achieved, proceed to step 2; statin prescription if >10 years of age to achieve tier I treatment goals.
- If initial BP is >90th percentile: step 1 management plus no added salt, increased activity for 6 months.

- BP consistently >95th percentile for age, sex, and height: initiate angiotensin-converting enzyme inhibitor therapy with BP goal <90th percentile or <130/80 mm Hg, whichever is lower.

#### CHRONIC KIDNEY DISEASE OR END-STAGE RENAL DISEASE

- Optimize renal failure management with dialysis or transplantation as per nephrologist.
- Assess body mass index, BP, lipids, fasting glucose: step 1 management for 6 months.
- If goals not achieved, proceed to step 2; statin prescription if >10 years of age to achieve tier I treatment goals.

#### AFTER HEART TRANSPLANTATION

- Optimize antirejection therapy, treatment for cytomegalovirus, routine evaluation by angiography or perfusion imaging per transplant physician.
- Assess body mass index, BP, lipids, fasting glucose; initiate step 2 therapy, including statins, immediately in all patients older than 1 year of age to achieve tier I treatment goals.

#### KAWASAKI DISEASE WITH CORONARY ANEURYSMS

- Antithrombotic therapy, activity restriction, ongoing myocardial perfusion evaluation as per cardiologist.
- Assess body mass index, BP, lipids, fasting glucose: step 1 management for 6 months.
- If goals not achieved, proceed to step 2; prescribe statins if older than 10 years of age to achieve tier I treatment goals.

BP, blood pressure; HbA1c, hemoglobin A1c; LDL-C, low-density lipoprotein cholesterol.

From Kavey R-EW, Allada V, Daniels SR, et al. Cardiovascular risk reduction in high-risk pediatric patients: a scientific statement from the American Heart Association Expert Panel on Population and Prevention Science; the Councils on Cardiovascular Disease in the Young, Epidemiology and Prevention, Nutrition, Physical Activity and Metabolism, High Blood Pressure Research, Cardiovascular Nursing, and the Kidney in Heart Disease; and the Interdisciplinary Working Group on Quality of Care and Outcomes Research: endorsed by the American Academy of Pediatrics. *Circulation*. 2006;114(24):2710–2738. © American Heart Association, Inc. Reprinted with permission.

included recommended values for non-HDL-C which are associated with persistent dyslipidemia, atherosclerosis, and future cardiac events. In practical terms, it can be measured in a non-fasting state. Normative values for other lipid particles, including HDL, apoprotein A-1 and apoprotein B, have been provided, but the Panel only made recommendations for treatment values on LDL-C, TG, and non-HDL-C (Table 286-2).

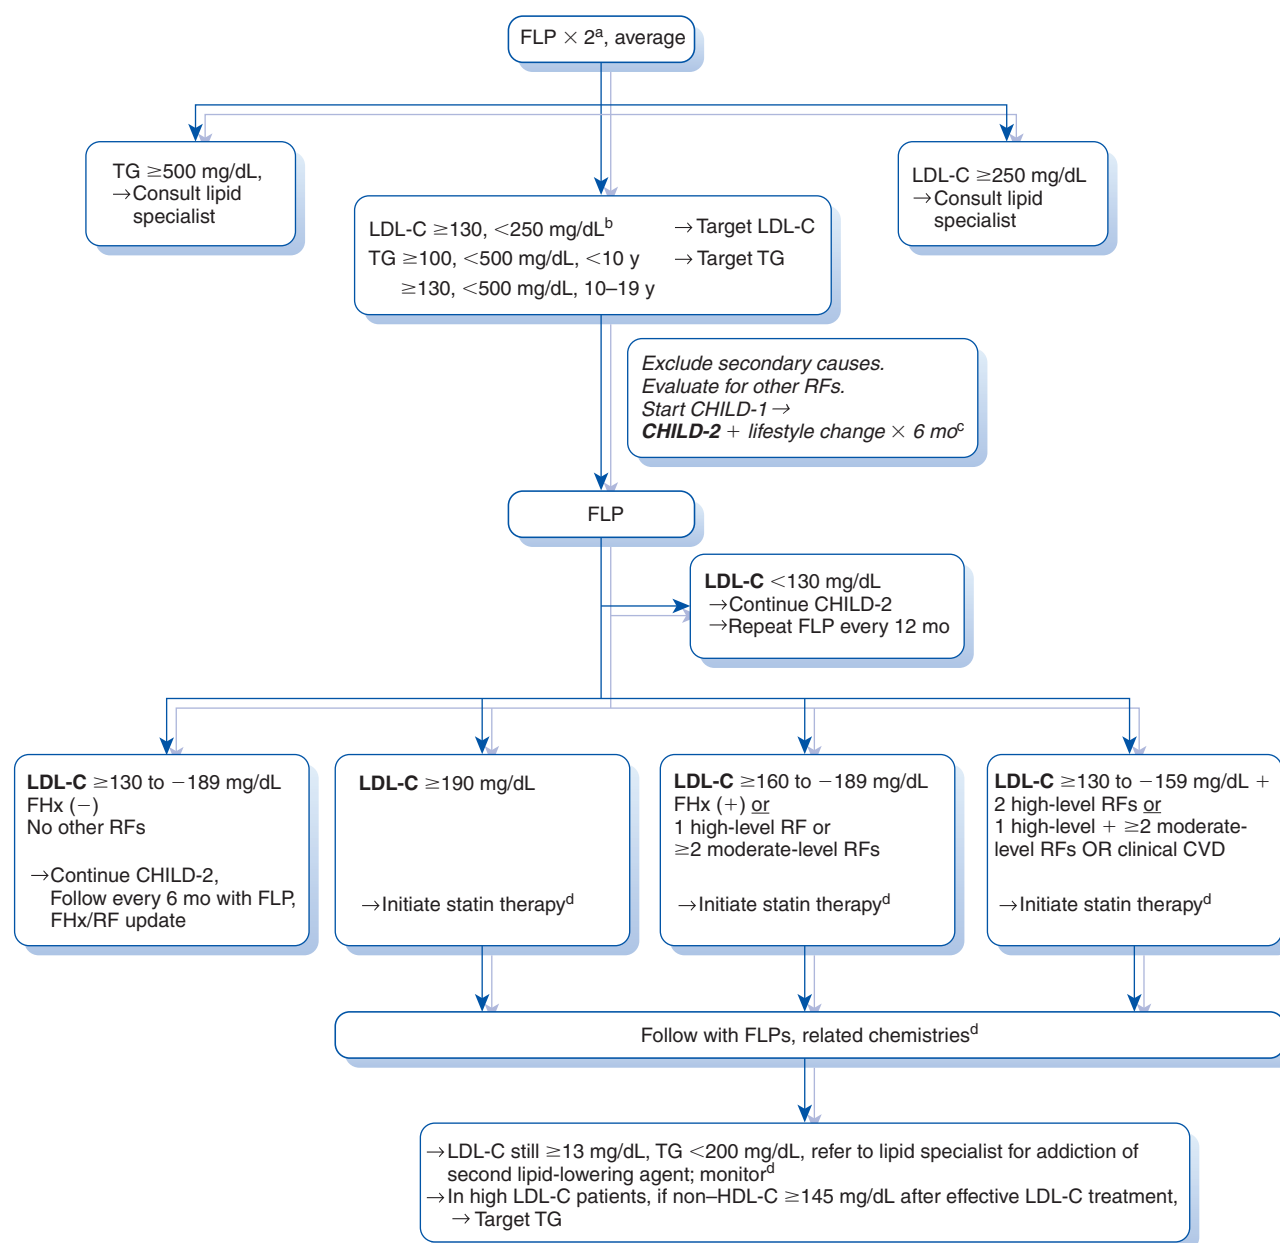

The determination for treatment should be based on the average of at least 2 LDL-C measurements, from fasting lipid panels taken at least 2 weeks, but no more than 3 months, apart, and treatment should follow the general strategy described below and in Figure 286-2:

- For acceptable levels (LDL-C <110 mg/dL) and for borderline levels (LDL-C 110 to 129 mg/dL): Advise the family to follow the CHILD-1 Diet, provide advice regarding other risk factors, and re-evaluate

the child at the next appropriate age cohort (17 to 21 years) or as per adult guidelines.

- For high levels (LDL-C  $\geq$ 130 mg/dL): Obtain a history detailing the use of drugs, such as isotretinoin (Accutane), steroids, and alcohol, to identify any secondary cause of hypercholesterolemia. In addition, screen for other secondary causes of elevated cholesterol, such as liver, thyroid, and renal disease (see Box 286-5).
- Hypertriglyceridemia is also a target for treatment. Referral to a lipid specialist should be considered when greater than 500 mg/dL (see Figure 286-3).

The initial dietary treatment is to follow a CHILD-2 Diet (see Table 286-3). This diet is safe and efficacious for managing children with borderline to high LDL-C levels. However, the child must consume adequate calories while decreasing fat intake. Current dietary guidelines suggest that all children should consume enough calories to reach or maintain desirable weight.

**Figure 286-2** Dyslipidemia algorithm: target LDL cholesterol. Values given are in mg/dL. To convert to SI units, divide results for TC, LDL cholesterol, HDL cholesterol, and non-HDL cholesterol by 38.6; for triglycerides, divide by 88.6. C, cholesterol; FHx, family history; FLP, fasting lipid profile; RF, risk factor; TG, triglycerides. <sup>a</sup>Obtain FLPs at least 2 weeks but no more than 3 months apart. <sup>b</sup>Use of drug therapy is limited to children aged 10 years and older with defined risk profiles. <sup>c</sup>In a child with an LDL cholesterol level of >190 mg/dL and other risk factors, a trial of the CHILD-2-LDL may be abbreviated. <sup>d</sup>For more details on statin initiation and monitoring, please see Table 9-11 and 9-12 in the source. (From Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents. Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents: summary report. Pediatrics. 2011;128(suppl 5):S213–S256.)

With the increase in the prevalence of overweight and obesity in children, weight reduction in these children often helps correct cholesterol profiles. However, in contrast to adults, some children with hypercholesterolemia are not overweight, and in children who are not overweight, caloric restriction is not the primary treatment for hypercholesterolemia, as it is often for adults.

The CHILD-2 Diet (see Figure 286-4), with no more than approximately 30% of calories from total fat (similar to the CHILD-1 Diet) and less than 7% of calories (compared with 10% in CHILD-1 Diet) from saturated fat, is advised (see Table 286-3). Adherence to the CHILD-2 Diet is often improved by having the family meet with a registered dietitian trained in managing hyperlipidemia in children. Nonpharmacologic

### BOX 286-5 Causes of Secondary Hypercholesterolemia in Children

Modified from American Academy of Pediatrics. National Cholesterol Education Program: Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. *Pediatrics*. 1992;89(3 Pt 2):525–584.

treatment can include increasing supplemental fiber intake calculated as the child's age plus 5 g/day, up to a dose of 20 g/day at 15 years of age. Consider drug treatment with binding resins, such as cholestyramine or colestipol, for children older than 10 years whose LDL-C level remains above 190 mg/dL after 6 to 12 months of dietary therapy. Medications should also be considered for those who maintain a level of LDL-C above 160 mg/dL and who have a family history of premature cardiovascular disease (see Figure 286-4).

Commercially available dietary products, such as special margarines with plant sterols and stanols to reduce LDL-C absorption, are available in supermarkets; however, the 2005 AHA/AAP Dietary Recommendations caution against using these spreads, given the possible decrease in absorption of fat-soluble vitamins and beta-carotene. Other medications, such as 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (HMG CoA-reductase inhibitors, or statins) are not routinely recommended for children except in consultation with a lipid specialist. The 2008 AAP Recommendations suggest lowering the statin treatment

age from 10 to 8 years old, based on experience in treating children with familial hypercholesterolemia. The NIH Panel adds that treatment should be considered when the LDL-C does not improve after diet intensification and the child has high-risk features. A 2014 Cochrane review of the same studies echoed the short-term safety but called into question the unknown implications of long-term exposure.

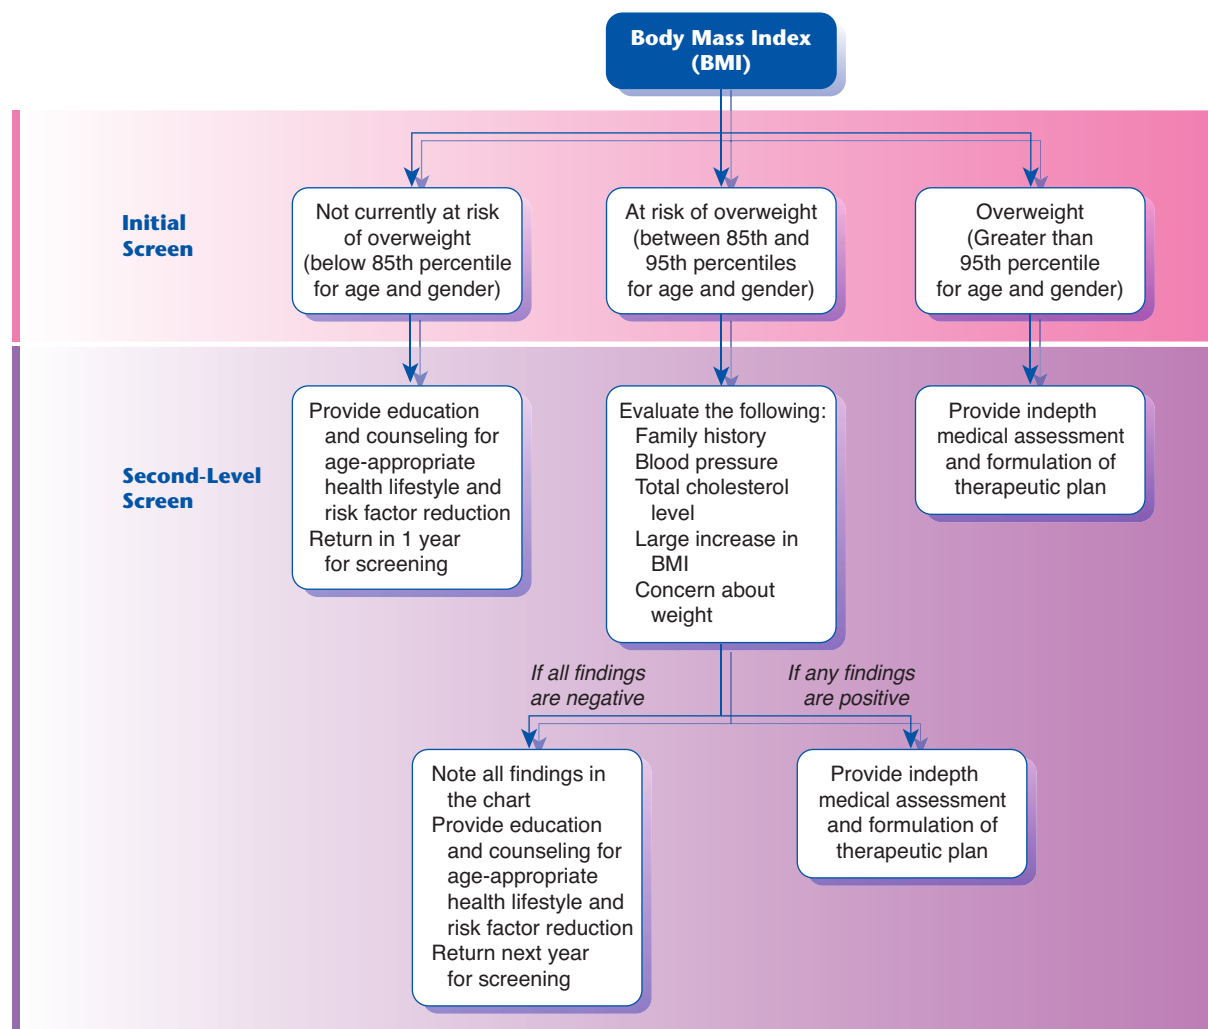

Cholesterol screening and dietary treatment guidelines can be initiated safely by a pediatrician (see Figure 286-1 and Figure 286-2) interested in nutrition and the prevention of heart disease. Initiation includes a review of family history, evaluation for secondary causes of hyperlipidemia (see Box 286-5), and dietary counseling. In addition, identifying children who have risk factors for coronary heart disease should lead to screening other family members, including parents, because many risk factors tend to cluster in families. If the primary care pediatrician is not comfortable managing children who have severe hypercholesterolemia that is unresponsive to dietary treatment or children who are from families with early-onset heart disease, then evaluation by a lipid specialist with continued general support from the pediatrician is recommended.

### OBESITY AND PHYSICAL ACTIVITY

Obesity increases the risk for heart disease through its association with abnormalities such as dyslipidemia, hypertension, insulin resistance, glucose intolerance, and possibly through other, as yet undefined, mechanisms that some refer to as "metabolic syndrome." The magnitude of the effect of childhood obesity on cardiac risk is an area of intense investigation with substantial implications for health, as summarized by the AHA. For example, the PDAY study found that body mass index and the thickness of the panniculus adiposus (ie, subcutaneous fat as measured by a skin-fold test) were correlated with the degree of coronary atherosclerosis in young adults. Several studies have suggested a relationship between the degree of obesity and abnormal lipid profiles.

The standard definition of obesity in children is based on age and sex percentiles of BMI, which is easy to calculate ( $BMI = \text{weight [kg]} / \text{height}^2[\text{m}]$ ). Children who have a BMI at the 95th percentile or higher are considered obese, and those with a BMI between the 85th and 95th percentiles are considered overweight. The terms *overweight* and *obesity* are often used interchangeably, a fact that should be kept in mind when reading the scientific literature.

Charting BMI by age and sex should be a part of every primary care physician's practice. Free templates can be obtained online from the Centers for Disease Control and Prevention. On the basis of the strong association between adiposity in childhood and adiposity in adulthood, and using BMI as a measure of obesity, the US Preventive Services Task Force in 2010 changed its recommendation for screening children for obesity, that physicians screen children aged 6 years and older and offer or refer them to comprehensive, intensive behavioral interventions to promote improvement in weight status (Grade B Recommendation). Current recommendations

**Figure 286-3** Evaluation of overweight in children.

from the AHA and AAP suggest that pediatricians should chart BMI, beginning at 2 years of age, and counsel parents to address the eating and activity patterns of at-risk children (see Chapter 35, Healthy Weight).

Body mass index can be easily calculated and plotted for all children (see Table 286-1). Obese children should be further screened for hypertension, orthopedic problems, hypoventilation, and abnormalities of lipids and glucose metabolism (see Figure 286-3). Additional specialty evaluations should be considered in individual situations, with the magnitude of the abnormalities being an important consideration. No single treatment program for overweight children has been uniformly successful. The first-line approach is diet and exercise therapy with behavioral modification and family counseling.

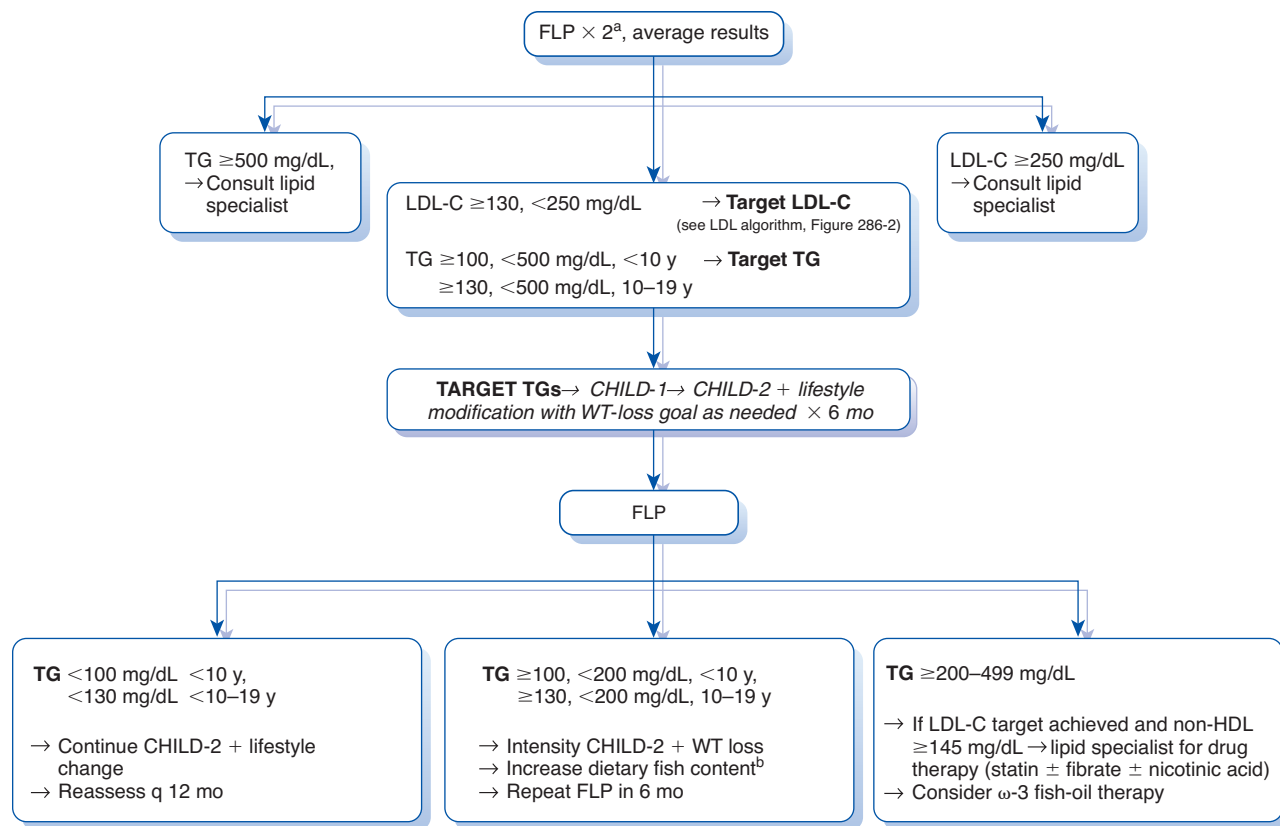

The AHA Scientific Statement on Metabolic Syndrome does not recommend a specific treatment, instead opting for the general approach of reducing obesity, increasing physical activity, and achieving blood pressure and lipid goals. However, the component

signs and symptoms of metabolic syndrome cluster in overweight children.

The importance of physical activity in preventing or ameliorating other cardiac risk factors, such as obesity, hyperlipidemia, and hypertension, has been recognized increasingly over the past several years. Furthermore, in adults, higher levels of physical activity have been associated with decreased rates of heart disease, above and beyond those associated with changes in known cardiac risk factors.

Health care professionals should encourage children of all ages to make physical activity a part of their daily routine (see Box 286-6). Children and their families should be encouraged to be physically active, and children are more likely to be physically active if their parents are active (see Table 286-1). Recent recommendations by the AHA and endorsed by the AAP stress the importance of age-appropriate physical activity. For example, school children should participate in regular physical activity most days of the week for at least 1 hour per day and should limit “screen time” (television, video game, and computer time) to less

**Figure 286-4** Dyslipidemia algorithm: target triglycerides. Values given are in mg/dL. To convert to SI units, divide results for TC, LDL cholesterol, HDL cholesterol, and non-HDL cholesterol by 38.6; for triglycerides, divide by 88.6. C indicates cholesterol; a Obtain FLPs at least 2 weeks but no more than 3 months apart. b The FDA and the Environmental Protection Agency advise women of childbearing age who may become pregnant, pregnant women, nursing mothers, and young children to avoid some types of fish and shellfish and to eat fish and shellfish that are lower in mercury. For more information, call the FDA's food information line toll-free at 1-888-SAFEFOOD or visit [www.cfsan.fda.gov/~dms/admeHg3.html](http://www.cfsan.fda.gov/~dms/admeHg3.html). than 2 hours per day. Children involved in competitive athletics should be counseled on issues related to weight control and strength training.

## SMOKING

The evidence that cigarette smoking is a risk factor for cardiovascular disease is overwhelming. Studies as early as 1940 documented a relationship between tobacco use and coronary artery disease. In 1964, the Surgeon General first reported the link between smoking and heart disease. In 1979, the Surgeon General addressed the growing problem of children who smoked or were exposed to smoke and, in 1994, addressed the need for smoking prevention in young people. A 1996 AHA task force presented more evidence that tobacco use increases the risk for cardiovascular disease.

Tobacco use adversely affects lipid levels and is associated with decreased exercise capacity, increased platelet aggregation, an increased incidence of respiratory illness, an increased incidence of low-birth-weight deliveries, and increased infant mortality. In addition, exposure to passive smoking is linked with

increases in risk factors for vascular and coronary artery disease in children. Passive smoking is associated with reduced HDL-C in nonsmoking children, as well as in those with high-risk lipid profiles. In 2006, the Surgeon General updated recommendations to eliminate secondhand or passive smoke exposure for children. The most recent AAP recommendation in 2009 continues its firm stance against smoking initiation and exposure to secondhand smoke.

Adolescents are more likely to smoke or use tobacco than any other age group. In 2009, the National Youth Tobacco Survey estimated that 8% of middle school and 24% of high school students were current users of tobacco products. However, the National Youth Risk Behavior Survey, 1991 to 2009, showed a decline in self-reported current tobacco use and in the frequency of use among high school students. The risk for smoking initiation increases from ages 12 to 16 years, with most adolescents initiating and becoming addicted during this critical period of development. Although most youth do not become nicotine dependent until after 2 to 3 years of smoking, addiction can occur after smoking as few as 100 cigarettes.

**BOX 286-6 Guidelines for Healthy Physical Activity Among Children**

Physicians and health care professionals should promote active healthy living within each family by

- Serving as role models for leading an active lifestyle.
- Inquiring about nutritional intake, calculating and plotting body mass index, identifying obesity-related comorbidities, and promoting healthy behaviors.
- Documenting the number of hours per day spent on sedentary activities and limiting screen time (television, video game, and computer) according to the AAP guidelines.
- Determining physical activity levels of the child and family members at regular health care visits.
- Tabulating the amount of daily physical activity each child or adolescent does at home, at school, or at child care as part of transportation, work, recreation, and unorganized sports. Tabulations should include the actual minutes each week of formal physical education and recess-related physical activity. In addition, the number of times per week spent in outdoor play for at least 30 minutes or the number of daily steps taken (as determined with a pedometer) should be documented. Specific involvement in organized sports and dance also should be noted.
- Encouraging children to be active for a total of at least 60 minutes a day, either continuously or cumulatively. Activities should be varied and of moderate intensity and may include sports, recreation, walking, chores, work, planned exercise, and school-based physical education classes. Activities should be fun to achieve best results.
- Identifying barriers to increasing physical activity, such as lack of time, competing interests, perceived lack of motor skills, fear of injury, and parental concerns about financial and safety issues.
- Educating the family about the importance of lifelong physical activity and helping them to identify strategies to overcome barriers.
- Recommending that parents become good role models by increasing their own level of physical activity, especially with activities that involve the entire family. Encourage children to play outside as much as possible, and to use appropriate safety measures, such as bicycle helmets, elbow and kneepads, life jackets, etc).
- Supporting children in participating in developmentally and age-appropriate sports and recreational activities, especially those favored by the child. These activities might occur during extracurricular activities in which parents or grandparents can take part as leaders and coaches.
- Suggesting that overweight children partake in activities that take advantage of their height and strength, such as water-based sports and strength training, rather than those that require weight bearing (eg, jumping, jogging).
- Recommending that parents of overweight children and youth play a supporting, accepting, and encouraging role in returning them to healthier lifestyles to increase self-esteem.
- Encouraging youth to promote physical activities among their peers and become role models and leaders for younger students.

Modified from American Academy of Pediatrics Council on Sports Medicine and Fitness and Council on School Health. Active healthy living: prevention of childhood obesity through increased physical activity. *Pediatrics*. 2006;117:1834–1842.

Children whose parents or siblings smoke are at an increased risk for beginning to smoke. Other factors that may predict smoking include peer influence, lower socioeconomic status, psychiatric and substance abuse disorders, Alaskan native and Native American ethnicity, and military service. Identifying these factors and addressing them openly is helpful in counseling. Primary care physicians should advise parents who smoke about the risks and refer them to a smoking cessation program. Pediatricians should actively participate in and support school and community antismoking campaigns. Although the current decline in the prevalence of smoking among children is a positive change, the potential for addiction brings smoking prevention into the realm of pediatric practice. The risks of smoking should be a part of routine preventive care discussions (see Table 286-1).

## CONCLUSION

Given the prevailing evidence from adults with atherosclerotic cardiovascular disease, the presence of risk factors in children, and the emerging data from long-term studies on cardiovascular disease outcomes in adults with childhood risk factors, pediatric primary care physicians should identify and treat these risk factors in children. Even more important, these physicians

can educate children and families about strategies to prevent the development of these risk factors and their continued presence into adulthood.

## Chapter 287 LYME DISEASE

H. Cody Meissner, MD

### EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Lyme disease was first recognized in 1975 after an investigation of a cluster of arthritis cases among children in Lyme, Connecticut, and soon thereafter the

black legged deer tick *Ixodes scapularis* was implicated as the vector of this disease. In 1982 a previously unrecognized spirochete, *Borrelia burgdorferi*, was detected in the midgut of the tick and identified as the etiologic agent. In 2013, more than 25,000 cases of Lyme disease were reported to the Centers for Disease Control and Prevention (CDC), making this condition the most common tickborne infectious disease in the United States. Because of under-reporting, it is likely that more than 10 times this number actually occurred. Although Lyme disease has been reported in almost every state, 95% of all cases are concentrated in 11 states from 3 geographic regions: the Northeast from Maine to Maryland, the Midwest in Wisconsin and Minnesota, and the West in Northern California and Oregon. The occurrence of disease corresponds with the distribution of the tick vectors *I. scapularis* in the East and Midwest and *I. pacificus* in the West. *B. burgdorferi* live in mice, squirrels, and other small animals and are transmitted among these animals and to humans by the bite of the tick. The tick lives for 2 years and has 3 stages: larvae, nymph, and adult. A blood meal is required at each stage of development. When the tick feeds on an infected animal, the spirochete is acquired, and when the tick feeds again the spirochete can be transmitted to a new host. Most cases of human Lyme disease are acquired in June, July, or August, when the nymphal stage is most active and human outdoor activity is greatest. Although deer are important for maintaining the tick population, deer do not become infected by the spirochete. *B. burgdorferi* have been divided into 3 pathogenic groups: North American strains belong to the group *B. burgdorferi sensu stricto* while most isolates from Europe and Asia are classified as *B. garinii* or *B. afzelii*.

### CLINICAL MANIFESTATIONS

Because the clinical manifestations of Lyme disease vary with the time that elapses after inoculation by the tick, the infection has been divided into early localized (stage 1), early disseminated (stage 2), and late phases (stage 3).

#### Early Localized Phase

Erythema migrans (EM) is the most common manifestation of early Lyme disease. Approximately 70% to 80% of patients exhibit or have a history of a skin lesion at the site of the tick bite. The macule gradually expands over several days to a large erythematous lesion that may increase in size to 5 cm or greater, sometimes with central clearing. Early lesions may not have central clearing or the characteristic target-like appearance. The rash may be warm but is not painful. Influenza-like symptoms that include malaise, fatigue, headache, arthralgia, myalgia, fever, or regional lymphadenopathy may accompany the skin lesion. Cough, rhinorrhea, vomiting, or diarrhea are not typical. The rash typically appears within 7 to 14 days (range 3 to 32 days) of the tick bite and, if untreated, resolves within 3 to 4 weeks.

#### Early Disseminated Phase

In the absence of antimicrobial therapy, hematogenous spread of the spirochete may occur, producing

the disseminated phase of early Lyme disease. Within days or weeks, in an untreated person, early disseminated disease may produce influenza-like symptoms including arthralgia, myalgia, headache, and fatigue. Other symptoms that may occur in this stage include multiple secondary EM lesions, Bell palsy, lymphocytic meningitis, or conjunctivitis. Serum antibody to *B burgdorferi* is usually not present during this stage of early disease, requiring 3 to 4 weeks to appear. However, the spirochete is cultured from the skin more easily during early infection than at any other time in the illness.

Months after onset of illness, approximately 60% of untreated patients will develop monoarticular or oligoarticular arthritis, which generally involves 1 or more large joints, especially the knees. Approximately 5% to 10% of untreated patients will develop neurologic manifestations within weeks of the early disseminated phase. Nervous system involvement may include cranial neuropathy (especially unilateral or bilateral facial palsy) and radiculopathy. Central nervous system involvement may include lymphocytic meningitis. Encephalopathy associated with late-stage Lyme disease, consisting of mild abnormalities of memory and cognitive function, is poorly understood and rare. Less than 5% of untreated patients will develop cardiac disease. Cardiac involvement is characterized most commonly by varying degrees of atrioventricular block but may include myopericarditis. Hospitalization is appropriate for patients with syncope, dyspnea, or chest pain. Complete heart block is usually brief, and only temporary cardiac pacing is needed. In untreated persons, symptoms involving the joints, central nervous system, or heart, reflecting spread of the spirochete to other parts of the body, may occur months after the tick bite.

### Late-Stage Disease

Among untreated patients, late-stage disease may produce recurrent oligoarticular arthritis that involves the knees. A small number of patients may develop neurocognitive symptoms, fatigue, difficulty with concentration, or sleep disturbances. These symptoms are not specific to Lyme disease. They may be triggered by a number of conditions and should not be referred to as chronic Lyme disease. Many of these patients have no evidence of previous or current infection by *B burgdorferi* and do not benefit from antimicrobial therapy.

### Congenital Infection

Although other spirochetal infections during pregnancy (eg, syphilis) can cause congenital infection, no causal relationship between maternal Lyme disease and congenital disease has been documented. No evidence exists to support transmission of *B burgdorferi* via human milk. Doxycycline should not be used to treat Lyme disease in pregnant or lactating patients.

### Coinfections

The same tick that transmits *B burgdorferi* also may transmit the agents of ehrlichiosis or anaplasmosis as well as the intraerythrocytic protozoa *Babesia microti* (the agent of babesiosis), either as a mixed infection or

as a single infection. Ehrlichiosis or anaplasmosis should be suspected in the appropriate epidemiologic setting in a patient with fever, chills, and headache in association with thrombocytopenia, leukopenia, or increased liver enzyme levels. Babesiosis in symptomatic patients may produce fever, malaise, chills, and sweats.

### Post-Lyme Syndromes

Considerable confusion surrounds the topic of post-Lyme disease syndromes. This is partly because of the lack of a widely accepted definition for this entity. A recent report from the Infectious Disease Society of America reviewed this issue and confirmed the following conclusions: (1) “there is no convincing biologic evidence for the existence of symptomatic chronic *B burgdorferi* infection among patients after receipt of a recommended treatment regimen for Lyme disease and (2) antibiotic therapy has not proven to be useful and is not recommended for patients with chronic (>6 months) of subjective symptoms after a recommended treatment regimen for Lyme disease.”

### DIFFERENTIAL DIAGNOSIS

In children who have what seems to be Lyme arthritis, the differential diagnosis may include oligoarticular juvenile arthritis, septic arthritis, and acute rheumatic fever. Other considerations in the differential diagnosis may include aseptic meningitis caused by enterovirus infection, Bell palsy caused by herpes simplex virus, varicella zoster virus, Epstein Barr virus or mycoplasma, a peripheral neuropathy not caused by *B burgdorferi*, or multiple sclerosis. Although such diagnoses are less likely after a history of a recent tick bite and EM, some patients with Lyme disease may offer no history of these events. Especially during summer months in an endemic area, Lyme disease should be considered in a patient who has lymphocytic meningitis or arthritis involving the knee.

### SEROLOGIC TESTING

Erythema migrans can be diagnosed in a person who lives in or has traveled to an endemic area and generally is a sufficient basis for a clinical diagnosis without laboratory confirmation. Serologic testing in a person with typical EM generally is discouraged because of the lack of sensitivity at this early stage of disease. As many as 60% of cases will have a false-negative antibody test result at this stage. However, not all patients with Lyme disease will develop EM, and many may not recall a tick bite. Isolation of *B burgdorferi* from a symptomatic patient is diagnostic of Lyme disease. However, culture media are not widely available and sensitivity is low.

Serologic testing may be useful in the few patients in whom a diagnosis is uncertain, particularly when symptoms have been present for more than several weeks. A 2-tier approach to serologic testing for Lyme disease should be used with both acute- and convalescent-phase serum specimens. Initial testing is most often conducted using an enzyme immunoassay (EIA). If positive or equivocal results are obtained, then a standardized Western immunoblot for both Lyme-specific immunoglobulin M (IgM) and IgG should

be performed, using the same serum specimen for tier 1 and tier 2 testing. A second step is necessary because false positive results are common with EIA resulting from cross-reactive antibodies. Based on CDC guidelines, an IgM immunoblot is considered positive if 2 of 3 bands are present. An IgG immunoblot is defined as positive if at least 5 of 10 bands are detected. In endemic areas, a positive immunoblot result is not always a result of an active *B burgdorferi* infection and may reflect previous infection. Two-tier testing should be used because of the high sensitivity but low specificity of the commercial enzyme immunoassays used in the first step. Testing by immunoblot should not be performed without first performing an enzyme immunoassay. The C6 peptide enzyme linked immunosorbent assay for measuring IgG antibody to a spirochete peptide is an acceptable alternative to 2-tier testing. Laboratory testing should not be performed for people who do not have symptoms of Lyme disease because of an increased likelihood of a false-positive test result. Testing of individual ticks is not useful for deciding whether antibiotic therapy should be initiated after a tick bite. Early antibiotic therapy may prevent seroconversion. Other laboratory tests such as urine antigen assays, immunofluorescence staining for cell wall deficient forms of *B burgdorferi*, and lymphocyte transformation assays have not been validated and should not be used.

## MANAGEMENT

### Pharmacotherapy

Patients with early localized or disseminated disease who do not have neurologic or cardiac involvement should be treated for 14 to 21 days with doxycycline (for children 8 years and older) except for pregnant or lactating women. An advantage of doxycycline is efficacy against the agent of human granulocytic ehrlichiosis, which may be a coinfecting microbe. Amoxicillin should be used for children younger than 8 years and in pregnant women. In patients who are unable to take doxycycline or amoxicillin, cefuroxime axetil is a third drug of choice. Clinical trials show resolution of symptoms in more than 90% of patients with EM treated with doxycycline, amoxicillin, or cefuroxime axetil. Macrolide antibiotics are less effective than other antimicrobial agents and should be reserved for patients who are unable to take preferred agents. Intravenous ceftriaxone is not superior to oral agents except in patients with neurologic or cardiac involvement.

Oral antimicrobial agents are effective for treating multiple EM and uncomplicated Lyme arthritis. Oral agents can be used to treat most people with facial nerve palsy, but central nervous system involvement such as meningitis with pleocytosis or neurologic abnormality should be treated with parenteral antibiotic therapy. Although first-degree atrioventricular block usually responds to oral therapy, higher-grade blocks are usually treated with parenteral therapy with ceftriaxone or penicillin for at least part of the course. Persistent or recurrent arthritis should be treated with either parenteral ceftriaxone or penicillin. Specific dosages and durations are given in Table 287-1.

### Vaccine

In December 1998 the US Food and Drug Administration approved a vaccine against Lyme disease (LYMERix) for individuals 15 to 70 years of age, but the vaccine was withdrawn voluntarily by the manufacturer in 2002 and is no longer available.

### Prophylaxis After a Tick Bite

Clinical practice guidelines developed by the Infectious Diseases Society of America for prevention of Lyme disease after a tick bite suggest that the following conditions be satisfied: (1) The biting tick is identified as *I scapularis*, with an estimated attachment time of more than 36 hours based on the size of the engorged tick, (2) prophylaxis can be started within 72 hours of tick removal, (3) local rates of tick infection by *B burgdorferi* exceed 20%, and (4) the use of doxycycline is not contraindicated. Doxycycline is the only antibiotic shown to be effective for postexposure prophylaxis. If doxycycline is administered for prophylaxis, a single 200 mg dose (4.4 mg/kg for body weight <45 kg) for people 8 years of age or older is recommended by some experts. No data are available to support amoxicillin use in this setting.

## PREVENTION OF TICK BITES

Ticks are most likely to be located in wooded and bushy areas with high grass. When walking in a tick-infested area, people should walk in the center of the path to avoid contact with grass and brush. Insect repellent containing DEET should be applied to skin and clothing. DEET-containing compounds can be used for children older than 2 months, should not be applied to the face or hands, and should be removed from skin with soap and water once the risk of exposure is over. Permethrin kills ticks on contact and can be applied to clothing but should not be applied directly to skin because it is inactivated by skin lipids. Long pants and sleeves will help keep ticks off skin, and light-colored clothing makes the task of spotting ticks easier. Daily tick checks should be performed. If a tick is attached for less than 24 hours, then the risk of acquiring Lyme disease is extremely small. Attached ticks should be removed as soon as possible using fine-tip forceps at the point of attachment. The overall risk of acquiring Lyme disease following a tick bite in a highly endemic area is 1% to 3%.

### WHEN TO REFER

- Cardiac involvement (heart block, pericarditis, myocarditis)
- Neurologic involvement (except isolated facial palsy in patients with definite Lyme disease diagnosis)
- Nonspecific clinical history but positive or equivocal laboratory testing
- Persistent arthritis

### WHEN TO ADMIT

- Cardiac involvement
- Meningitis or encephalopathy

**Table 287-1** Treatment Regimens for Lyme Disease

DISEASE CATEGORY	DRUG(S) AND DOSE <sup>a</sup>
<b>EARLY LOCALIZED DISEASE<sup>a</sup></b>	
8 years or older	Doxycycline, 4 mg/kg per day, orally, divided into 2 doses (maximum 200 mg/day) for 14 days <sup>b</sup>
Younger than 8 years or unable to tolerate doxycycline <sup>b</sup>	Amoxicillin, 50 mg/kg per day, orally, divided into 3 doses (maximum 1.5 g/day) for 14 days <b>OR</b> Cefuroxime, 30 mg/kg per day in 2 divided doses (maximum 1000 mg/day or 1 g/day) for 14 days
<b>EARLY DISSEMINATED AND LATE DISEASE</b>	
Multiple erythema migrans	Same oral regimen as for early localized disease, for 14 days
Isolated facial palsy	Same oral regimen as for early localized disease, for 14 days (range 14–21 days) <sup>c,d</sup>
Arthritis	Same oral regimen as for early localized disease, for 28 days
Recurrent arthritis	Same oral regimen as for first-episode arthritis, for 28 days <b>OR</b> Preferred parenteral regimen: Ceftriaxone sodium, 50–75 mg/kg, IV, once a day (maximum 2 g/day) for 14 days (range 14–28 days) Alternative parenteral regimen: Penicillin, 200 000–400 000 U/kg per day, IV, given in divided doses every 4 hr (maximum 18–24 million U/day) for 14 days (range 14–28 days) <b>OR</b> Cefotaxime 150–200 mg/kg per day, IV, divided into 3 or 4 doses (maximum 6 g/day) for 14 days (range 14–28 days) Symptomatic therapy
Antibiotic-refractory/persistent arthritis <sup>e</sup>	
Atrioventricular heart block or carditis	Oral regimen as for early disease if asymptomatic <sup>f</sup> or not hospitalized, for 14 days (range 14–21 days) <b>OR</b> Parenteral regimen initially for hospitalized patients, dosing as for recurrent arthritis, for 14 days (range 14–21 days); oral therapy can be substituted to complete the 14–21 day course
Meningitis	Ceftriaxone <sup>g</sup> or alternatives of cefotaxime or penicillin <sup>g</sup> : dosing as for recurrent arthritis, for 14 days (range 10–21 days) <b>OR</b> Doxycycline, 4–8 mg/kg per day, orally, divided into 2 doses (maximum 100–200 mg for 14 days (range 14–21 days) <sup>b</sup>
Encephalitis or other late neurologic disease <sup>h</sup>	Ceftriaxone <sup>g</sup> or alternatives of cefotaxime or penicillin <sup>g</sup> : dosing as for recurrent arthritis, for 14 days (range 14–28 days)

IV, intravenously.

<sup>a</sup>For patients who are allergic to penicillin, alternatives are cefuroxime, azithromycin, and erythromycin.

<sup>b</sup>Tetracycline-based antimicrobial agents, including doxycycline, may cause permanent tooth discoloration for children younger than 8 years if used for repeated treatment courses. However, doxycycline binds less readily to calcium compared with older tetracyclines, and in some studies, doxycycline was not associated with visible teeth staining in younger children.

<sup>c</sup>Corticosteroids should not be given.

<sup>d</sup>Treatment has no effect on the resolution of facial nerve palsy; its purpose is to prevent late disease.

<sup>e</sup>Arthritis is not considered persistent unless objective evidence of synovitis exists at least 2 months after completion of a course of parenteral therapy or of two 28-day courses of oral therapy. Some experts administer a second course of an oral agent before using an IV-administered antimicrobial agent.

<sup>f</sup>Symptoms for heart block or carditis include syncope, dyspnea, or chest pain.

<sup>g</sup>For treatment of meningitis or encephalitis with ceftriaxone, cefotaxime or penicillin, drug should be administered IV.

<sup>h</sup>Other late neurologic manifestations include peripheral neuropathy or encephalopathy.

## Chapter 288

## MEDICAL ERRORS, ADVERSE EVENTS, AND PATIENT SAFETY

Daniel R. Neuspiel, MD, MPH

Patient safety is the freedom from accidental or preventable injuries produced by medical care. (This should be distinguished from home and community injury prevention, another important role of pediatricians in ensuring child safety.) In 1999, the Institute of Medicine published the landmark report, *To Err Is Human: Building a Safer Health System*, which noted that errors caused by the health care system are a leading cause of death and injury. Medical errors in pediatrics cause significant harm, are costly, and are largely preventable.

Several terms are commonly used in patient safety and require definition (see Table 288-1). A *medical error* occurs when an act of commission or omission occurs that either causes an undesirable outcome or invokes risk for such an outcome. An *adverse event* (AE) occurs when injury or harm is caused by medical care. Adverse events may be *preventable*, when patient harm is related to a medical error, or *nonpreventable*, when patient harm occurs in the absence of a medical error. *Adverse drug events* are AEs caused by medication. A *near miss* is an error that does not result in an AE; also known as a “close call.” A *slip* is an error resulting from an unconscious lapse in otherwise automatic task performance caused by distraction, and may be considered a failure of execution. A *mistake* is an error resulting from an incorrect choice and is related to faulty knowledge, training, or information; it may be considered a failure of planning. Other terms are defined later in this chapter.

## EPIDEMIOLOGY

The epidemiology of medical errors in pediatrics may be categorized by type (eg, errors related to diagnosis, medication, surgery, technology, communication) as well as location (eg, inpatient, outpatient, emergency department, home, school). The relative incidence of various types of pediatric medical errors is not yet well established. Although most publications to date have focused on medication errors, it is not clear whether these are the most frequent types of errors in pediatrics.

## Diagnostic Errors

In a survey of 726 pediatricians and pediatric residents, 54% of physicians reported making a diagnostic error at least once or twice per month. The error rate among trainees was 77%. Errors harmful to patients occurred at least once or twice annually among 45% of respondents. The most frequently reported process lapse was failure to gather adequate clinical information. The most commonly reported system error was inadequate coordination of care and teamwork. Among specific errors, the most frequent were viral infections diagnosed as bacterial, followed by misdiagnosis of adverse reactions to medications, psychiatric disorders, and appendicitis.

In a systematic review of diagnostic errors in the neonatal intensive care unit (NICU) and the pediatric intensive care unit (PICU) settings, major diagnostic errors were found in 20% of autopsied PICU and NICU deaths. Although missed infections were most common in both settings, missed vascular events were more common in the PICU and missed congenital conditions in the NICU.

Reviews of closed pediatric malpractice claims indicate that the most frequent basis of these events was diagnostic error. Failure to correctly diagnose was listed as the primary issue in 36% of claims reported between 2003 and 2012. Among pediatric claims paid in 2012, 48% reported diagnostic error as the primary allegation. Among claims involving errors in diagnosis, meningitis was the most prevalent condition that was incorrectly diagnosed by pediatricians, followed by appendicitis, pneumonia and fever. Errors in diagnosing meningitis resulted in the highest percentage of paid claims (49%), and errors in diagnosing fever contributed the highest average payment (\$529,548).

## Medication Errors

Medication errors commonly affect children in the inpatient, outpatient, home, and school settings. Such errors occur at the stages of medication ordering, transcribing, dispensing, and administration. Children may be of particular risk for medication errors because of varied sizes, stages of development, communication barriers, and treatment by health care staff unfamiliar with this age group.

In the outpatient setting, as many as 15% of pediatric prescriptions have been reported to have dosing errors. Preventable adverse drug events have been reported to occur in 3% of children receiving prescriptions. Both errors and preventable adverse events occur more frequently among younger children and those receiving multiple prescriptions. Errors have been reported in 15% of pediatric emergency department prescriptions, higher among less experienced providers and on nights and weekends.

Children with special needs who take multiple medications seem to be at higher risk for home medication errors. These include children receiving outpatient oral chemotherapy for acute lymphoblastic leukemia, with an error rate of 19% over a 2-month period, related to incorrect dosing or failing to administer an indicated medication. Home medication use in children with cancer has been reported with an error rate of 70%; errors with injury 4%, and potential injury 36%. Among children with sickle cell disease and seizure disorders, 22% of reviewed home medications revealed medication errors, often consisting of failure to fill prescriptions or to change to new recommended dosing. Patients' physicians were unaware of 80% of the detected home medication errors. Errors have also been reported in medication prescriptions for children with depression and attention deficit/hyperactivity disorder.

Communication barriers between health care providers and the caregivers of children are important sources of error. The accuracy of liquid medication administration by parents varies from 15% to 50%. Calibrated syringes show the highest accuracy for home medication dosing. Over-the-counter liquid

**Table 288-1** Definitions in Patient Safety

TERM	DEFINITION	EXAMPLE
Adverse drug event	Adverse event caused by medication	Diarrhea caused by amoxicillin
Adverse event	An occurrence of injury or harm caused by medical care	Laceration caused by wall ophthalmoscope falling on infant
Cause-and-effect (fishbone or Ishikawa) diagram	A method to sort all possible causes of an error into useful categories	After serious adverse event, a team is assembled to conduct root cause analysis using a cause-and-effect diagram to assist their discussion
Clinical decision support	A system to improve clinical decision-making by providing direct access to evidence-based information	Electronic medical record includes feature that allows the physician to click on "diagnosis" to open a screen that shows recommendations from the latest AAP clinical practice guideline
Failure modes and effects analysis	A quality improvement process used to prospectively identify the risk of error within a process	To reduce inpatient pediatric prescribing errors, teams analyzed drug delivery process to identify potential failures and plan practice changes
Forcing function	A limit built into a process that prevents an action with high risk of error	Gastrostomy tubing cannot fit into intravenous port
Human factors science	A discipline that attempts to identify and address safety problems arising from the interaction between people, technology, and work environments	A human factors approach was used to analyze adverse events during pediatric cardiac surgery and found that communication breakdowns were a major cause
Medical error	An act of commission or omission that causes or entails risk of undesirable patient outcome	Vaccine given to wrong patient
Mistake	Error resulting from incorrect choice, related to faulty knowledge, training, or information; a failure of planning	Physician prescribes wrong antibiotic for infection
Near miss	Error that does not result in AE (ie, "close call")	Physician orders wrong vaccine, but the error is detected by a nurse before it is administered
Nonpreventable AE	Patient harm in the absence of medical error	Child on stimulant for attention deficit/hyperactivity disorder loses weight because of drug-induced appetite suppression
Preventable AE	Patient harm related to a medical error	Caused by lack of follow-up of newborn screening results, an infant with congenital hypothyroidism remains untreated for months and develops intellectual disability
Redundancy	Duplication of key part of process to reduce chance of error	Two nurses sign off on all chemotherapy orders before administration
Root cause analysis	A process of comprehensive investigation of all underlying causes of an error, emphasizing systems rather than individual performance	After serious medication error, a team of relevant staff is assembled to investigate possible causes and to recommend solutions to reduce or prevent recurrence of the error
Sentinel event	An unexpected occurrence involving actual or potential death or serious physical or psychological injury	Suicide of patient receiving around-the-clock care; infant abduction or discharge to wrong family; hemolytic transfusion reaction involving administration of blood or blood products with major blood group incompatibilities; surgery on wrong patient or body part; medication error resulting in major permanent loss of function or death
Serious reportable (never) event	An event that is unambiguous, serious, and usually preventable	Wrong-side surgery; invasive procedure on the wrong patient; death or serious injury caused by contaminated drugs or equipment; death caused by electric shock in health care setting

**Table 288-1** Definitions in Patient Safety—cont'd

TERM	DEFINITION	EXAMPLE
Six sigma	A quality improvement process that aims to reduce errors to approach <3.4 per million events	A children's hospital used six sigma approach to improve the accuracy of weight determination for pediatric burn patients to reduce medication and fluid administration errors
Slip	Error resulting from unconscious lapse in automatic task performance caused by distraction; a failure of execution	A physician intends to consult subspecialist about complex patient, but fails to do so because of distraction
Trigger tool	A measurable signal for detecting likely AEs	Using a Global Trigger Tool, investigators at a children's hospital detected incidence of harm 2 to 3 times higher than previously published pediatric rates

AAP, American Academy of Pediatrics; AE, adverse event.

The application of lean six sigma to provide high-quality, reliable pediatric care. *Int J Pediatr Adol Med*. 2014;1(1):8–10; and Kirkendall ES, Kloppenborg E, Papp J, et al. Measuring adverse events and levels of harm in pediatric inpatients with the Global Trigger Tool. *Pediatrics*. 2012;130(5):e1206–1214.

medications for children are often provided with highly variable and inconsistent dosing directions and measuring devices, which may contribute to errors. Information materials provided by pharmacies, if provided at all, are often at health literacy levels above those of parents. Caregivers with limited English proficiency have additional barriers in understanding medication instructions; even when pharmacies provide translated instructions, these often contain errors generated by interpretation software. Adolescents with less parental supervision may also have increased risk for home medication error.

In the pediatric inpatient environment, medication error rates have ranged from 5% to 27%. A systematic review reported that dosing errors were the most frequent type of inpatient pediatric medication errors, and the medications most often involved were antibiotics and sedatives. Increased risk for inpatient medication errors have been reported during evening and weekend shifts, possibly attributable to less availability of hospital pharmacists. Dosing errors have been reported to be higher in overweight and obese pediatric inpatients. There is often confusion of pounds and kilograms in calculating doses. Tenfold medication errors, involving the omission or addition of zeroes, are a frequent source of inpatient dosing error. These occur often because of incorrect programming of infusion pumps, overriding alarm limits, or paper-based ordering or in urgent situations. Tenfold errors are most frequently reported with opioid medications. Medication errors in the PICU are better detected by direct observation than voluntary reporting.

### Surgical, Anesthesia, and Intensive Care Errors

Little has been reported on errors related to pediatric surgery. A single study of 64 pediatric surgical patients during a 1-month period detected 108 errors, with 28% resulting in adverse outcomes. Among all

adverse events, 47% were attributed to medical errors. Among all patients, 67% experienced at least 1 error, and 33% had an adverse outcome. Most frequent errors were in communication, postoperative monitoring and care, and diagnosis.

In a children's hospital in the United Kingdom, 668 incidents related to pediatric anesthesia were reported, a rate of 2.4% of all anesthetics recorded. Most incidents were related to airway and respiratory system (52%). Most frequent human factors involved were errors in judgment (43%), failure to check (18%), technical failures of skill, such as errors in central venous access or airway management (9%), inexperience (8%), inattention or distraction (6%), and communication errors (6%).

Among 606 pediatric anesthesia incidents from a national reporting system in the United Kingdom, 6 resulted in deaths and 48 in severe harm. Medication errors were involved in 36% of incidents, especially duplication of dosing in the operating room and floor. Other errors involved airway/ventilation (19%), cardiovascular events (6%), failure or unavailability of equipment (16%), and communication or organizational problems (9%).

Using a voluntary reporting system, among 464 incidents from 23 PICUs, medication errors were the most frequent type. Line, tube, and airway incidents accounted for one-third, but with higher degree of harm than other incidents. A systematic review of incidents and error in the NICU also found medication errors to be most frequently reported. The error rate was much higher in studies using voluntary versus mandatory reporting.

### Serious Reportable and Sentinel Events

*Serious reportable events* (formerly known as *never events*) are AEs that are easily identified and measured, serious, and usually preventable. The National Quality Forum initially defined these events in 2002,

currently consisting of 29 events grouped into 6 categories: surgical, product or device, patient protection, care management, environmental, radiologic, and criminal. A current list of serious reportable events may be found at [www.qualityforum.org/Topics/SREs/Serious\\_Reportable\\_Events.aspx](http://www.qualityforum.org/Topics/SREs/Serious_Reportable_Events.aspx).

Since 1995, The Joint Commission has recommended hospital reporting of *sentinel events*, defined as unexpected events involving death or serious injury, or risk for such occurrences. Sentinel events include all serious reportable events. After a sentinel event occurs, The Joint Commission requires a *root cause analysis* (RCA) (see Management).

In 2007, the Centers for Medicare and Medicaid Services announced that Medicare would cease payment for additional costs that resulted from many preventable errors, including serious reportable events. Similar policies have been adopted by many states and private insurers. Many states also mandate public reporting of serious reportable events and other serious AEs.

### Errors Specific to Outpatient Pediatrics

In a study of 14 pediatric practices, 147 medical errors were reported. The largest group of errors was related to medical treatment (37%), but errors were also associated with patient identification (22%), preventive care, including immunizations (15%), diagnostic testing (13%), patient communication (8%), and other causes.

In an outpatient pediatric department with approximately 36,000 visits per year, 80 errors were reported over a 12-month period (2.2 errors reported/1,000 visits/year). Errors were classified as involving office administration (34%), medications and other treatment (24%), laboratory and diagnostic testing (19%), and communication (18%). The most frequent office administration errors included wrong demographic information or date of visit (9%), misfiled papers in medical records (9%), and delays in processing patients because of misplaced registration forms (9%). The most frequent errors attributed to medication and other treatment included miswritten vaccine and medication order near miss (6%), wrong vaccine administered (5%), wrong outside prescription dispensed (4%), incomplete prescription returned by pharmacy (4%), and patient revaccinated too early (4%). Among errors attributed to laboratory and diagnostic testing, the most common were missed specimen pickup (10%) and mislabeled specimens (4%). The most frequent communication errors were patients leaving the practice before ordered vaccines were administered (8%).

In a pediatric clinic with approximately 26,000 visits per year, there were 216 medical errors reported over 30 months (3.3 errors/1,000 visits/year). The most frequently reported errors were misfiled or erroneously entered patient information (31%), laboratory test delayed or not performed (13%), error in medication prescribing or dispensing (11%), vaccine error (10%), patient not given requested appointment or referral (7%), and delay in office care (7%).

### Errors in Emergency Department Setting

In the pediatric emergency department (ED), errors may occur related to a busy environment with frequent

interruptions, faulty communication during patient handoffs, provider fatigue, decision-making by multiple providers, many verbal orders, language barriers with patients, lack of familiarity of adult staff with children, and treatment outside of the patient's medical home with lack of access to medical records. Medications are often grabbed out of a medication dispensing cabinet before profiling by a pharmacist.

Medication errors in the pediatric ED setting have been described in 10% to 15% of opportunities, with higher risk when ordered by inexperienced trainees, outside of regular daytime hours, or for very ill children. Inaccurate dosing of acetaminophen by pediatric ED staff has been reported 22% of the time.

### Errors Related to Information Technology

Health information technology has been implicated in a new breed of medical errors. Commonly reported errors among these include computer or network malfunction, truncated input data, inability to order items, incorrect default dosages for medications, data entered under wrong patient name, incorrect merging of more than 1 patient's data, lack of follow-up of critical abnormal test result alerts, discontinuation of medication without notifying staff, and billing requirements leading to inaccurate documentation. Electronic health records may exacerbate the risk for error by physicians overlooking data that are difficult to locate. Precompleted templates may contain inaccurate information that is not deleted or outdated information that is copied forward from prior notes. Electronic notes may import test results that were not reviewed.

## DIAGNOSIS

### Error Reporting

Awareness of medical errors is dependent on a reliable reporting system. Error reports may be filed electronically by call-in or on paper. They may be *anonymous*, *confidential*, or *open*. Traditional hospital incident reporting systems are open, with all involved individuals identified. These are often perceived as punitive, are poorly used, and miss many clinically significant events. The Institute of Medicine recommends a blame-free nonpunitive error reporting system that includes both adverse events and near misses, and a systems-based approach to analyzing errors. Such an approach shifts the blame away from individuals and to faulty or inadequate systems that contribute to medical errors. The American Academy of Pediatrics emphasizes the importance of creating a patient safety culture in which providers and staff understand the importance of patient safety and in which constant attention is paid to avoiding errors.

Anonymous reporting has been advocated to promote more complete error reporting. Although easier in theory, anonymous reporting has some limitations. True anonymity may be compromised when data in the report provide enough information for others to identify the specific situation and individuals involved. Also, anonymous reports may omit important data about a particular adverse incident, and the reporter cannot be contacted for more details.

**BOX 288-1 Examples of Pediatric Trigger Tools**

- Episode of cardiopulmonary arrest
- Hospital readmission within 30 days
- Emergency department readmission within 48 hours
- Return to surgery
- Naloxone administration
- Apgar score of <7 at 5 minutes

Confidential reporting enables the ability to conduct follow-up interviews and obtain more information from those involved in a specific event by potentially eliminating the fear of reporting. The promise of confidentiality is based on the premise that data will be accessible only to those who need it. This requires staff and leadership commitment to a safety culture in which unintentional errors are not punished. However, staff may not entirely trust such a system, fearing the disclosure of confidential information that could lead to punishment or litigation. Also, when confidential data are collected and shared with a third party, there may be concerns about possible discovery during a lawsuit. In a “just” safety culture, the parties involved have reasonable protection from legal and other harms.

**Trigger Tools**

Trigger tools use recognized measurable indicators to monitor and detect medical errors and adverse events. Typically, a trigger tool analysis involves retrospective review of a random sample of patient records using “triggers” (or clues) to identify possible adverse events (see Box 288-1). Detailed trigger tools for use in the PICU setting are available (see Tools for Practice). To date, outpatient trigger tools have not been established in pediatrics.

**MANAGEMENT**

Reports of medical errors may be managed with several processes, including RCA, morbidity and mortality conferences, patient safety organizations (PSOs), disclosure, and apology, as described later.

**Root Cause Analysis**

An RCA is a comprehensive method to identify as many causes for the error as possible, going beyond simple explanations to digging deeply into all contributing factors. To be successful, this method requires skilled leadership and an interdisciplinary team that includes expertise and interests of all parties relevant to the event. The goal of RCA is to focus on systemic factors leading to the error in order to develop preventive strategies to avoid recurrences of similar events. When present, human error should also be addressed. A cause-and-effect (fishbone or Ishikawa) diagram is often used to assist in showing root causes into specific categories, such as measurement, materials, methods, environment, staffing, and equipment.

Figure 288-1 is an example of a partial cause-and-effect diagram for a RCA of a report of wrong vaccine administration.

**Morbidity and Mortality Conferences**

Traditional hospital morbidity and mortality conferences may be helpful ways to present medical errors in an educational forum. When performed under the hospital’s quality assurance process, morbidity and mortality conferences are protected from legal exposure.

**Patient Safety Organizations**

Authorized by the Patient Safety and Quality Improvement Act of 2005 to improve quality and safety of health care delivery in the United States (see [www.pso.ahrq.gov/statute/pl109-41.pdf](http://www.pso.ahrq.gov/statute/pl109-41.pdf)), PSOs allow individual physicians and health care organizations to voluntarily report and share medical errors in a framework that is protected from legal discovery. Eligible organizations may apply to become PSOs to create a secure environment to collect, aggregate, and analyze patient safety data in order to identify and reduce risks and hazards resulting from medical care. A current list of federally approved PSOs is available at [www.pso.ahrq.gov/listing/alphabet.htm](http://www.pso.ahrq.gov/listing/alphabet.htm).

**Error Disclosure and Apologies**

Following a significant medical error, patients and their families often express their desire to know what happened, why it happened, and what will be done so that it does not happen again. Establishing trust with families by initiating early and full disclosure may reduce tensions and save time, resources, and strain on families and physicians. Lack of communication about errors may make patients feel worse and lead to physician feelings of anxiety, unworthiness, and guilt. Pediatricians and institutions should develop policies and procedures for disclosing adverse events to families, as well as to children when age appropriate.

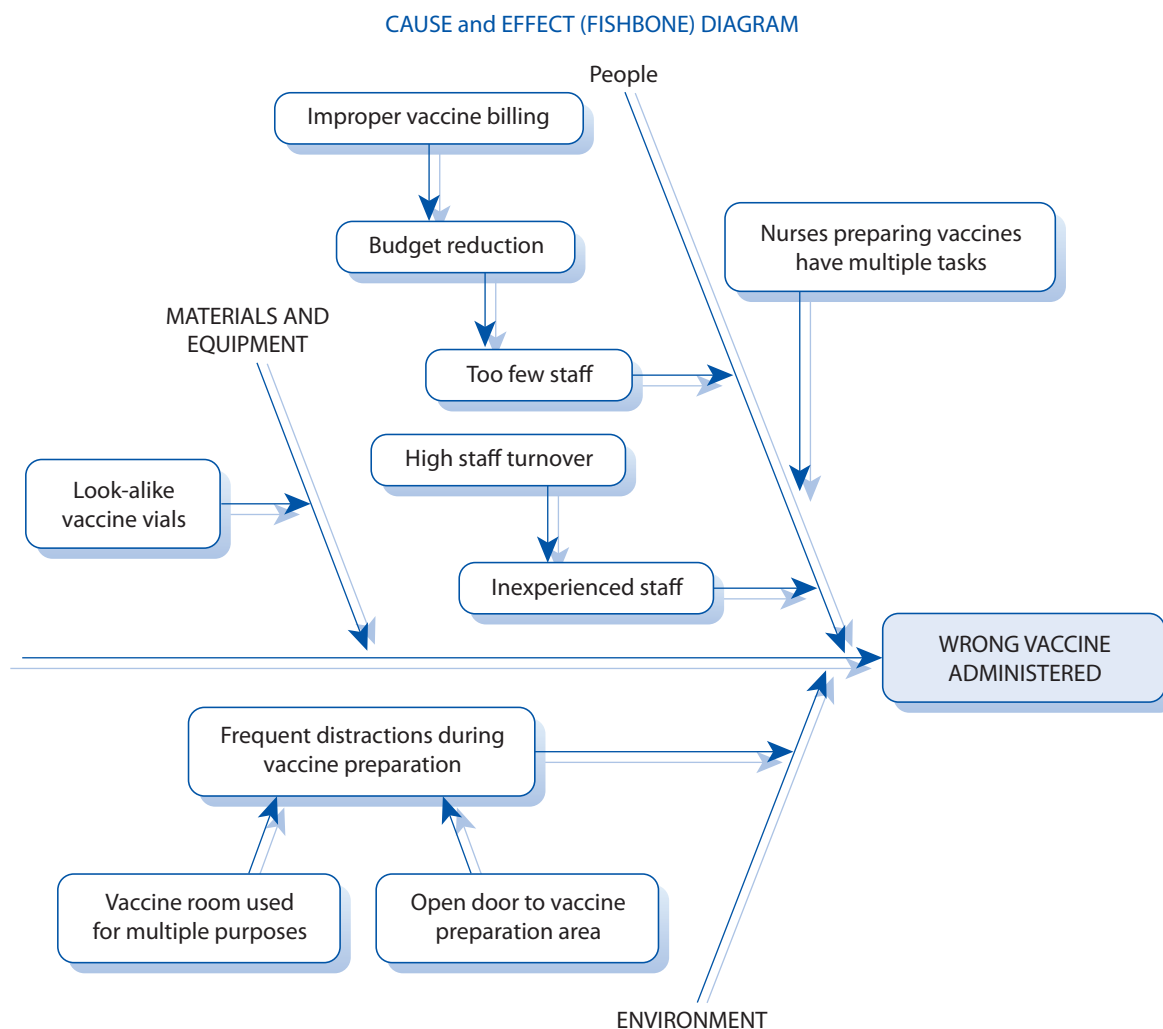

Physicians may hesitate to apologize about an error if doing so can be used as an admission of wrongdoing in a legal action. Acknowledging this phenomenon, many states enacted statutes protecting apologies from admission as evidence in malpractice litigation. Most states now have “apology laws” to protect a physician statement such as “I’m sorry,” but may not protect admissions of fault ([sorryworkssite.bondwaresite.com/apology-laws-cms-143](http://sorryworkssite.bondwaresite.com/apology-laws-cms-143)). Pediatricians and other child health care providers should discuss specific institutional policies and state disclosure statutes in effect with their malpractice carriers or risk managers.

**PREVENTION**

There are many ways that pediatricians and other physicians caring for children can improve patient safety and reduce the risk for adverse events. Efforts to prevent medical errors in pediatrics are multifaceted and are summarized in Table 288-2.

**Human Factors**

Human factors science is the study of designing systems and equipment to fit the human body and its cognitive abilities. It looks at the intersection of

**Figure 288-1** Cause-and-effect (fishbone) diagram.

people, technology, and work processes to design efficient, high-reliability systems with reduced chance of error.

### Design Modifications

Design and storage modifications to promote pediatric safety include changes to avoid confusion between look-alike, sound-alike medications for hospital and office staff, as well as smart infusion pumps in the inpatient setting. In the home setting, improving caregiver dosing tools may reduce medication errors. Including pictographic dosing diagrams with written medication instructions among parents with low health literacy reduced medication administration errors compared with text-only recipients. A sliding-card-based dosing tool was effective in improving accuracy of home administration of acetaminophen. Dosing errors by parents were more frequent with measuring cups compared with droppers, spoons, or syringes.

### Medication Reconciliation

*Medication reconciliation* may reduce medication errors, particularly during transitions of care. Since 2005, medication reconciliation has been a national

patient safety goal of the Joint Commission ([www.jointcommission.org/sentinel\\_event\\_alert\\_issue\\_35\\_using\\_medication\\_reconciliation\\_to\\_prevent\\_errors](http://www.jointcommission.org/sentinel_event_alert_issue_35_using_medication_reconciliation_to_prevent_errors)). This process compares a patient's medication orders to all the medications that the child has been taking. It is done to avoid medication errors, such as omissions, duplications, dosing errors, or drug interactions, and should be done at every transition of care when new medications are ordered or existing orders are rewritten. Transitions in care include changes in setting, service, physician, or level of care (see Box 288-2).

Medication reconciliation in pediatrics has primarily focused on the inpatient setting, but its use is also valuable in ambulatory care.

Errors may occur in the medication reconciliation process because of inaccurate medication histories. Parents may not be aware of the specific medications taken by their children. Some electronic health records may not automatically remove short-term medications from the child's medication list.

### Clinical Pharmacists

The presence of clinical pharmacists has been effective in reducing medication errors in the pediatric inpatient

**Table 288-2** Strategies to Improve Patient Safety

STRATEGY	INPATIENT EXAMPLE	OUTPATIENT EXAMPLE
Attention to human factors	Standardize devices in hospital to make training easier and increase reliability	Alcohol-based gel dispensers are placed at entry to all examination rooms
Design modifications of medications and dosing tools	Avoid colocating look-alike or sound-alike medications	Use standardized dosing syringes for all oral liquid medications
Regular medication reconciliation, especially after transitions of care	Conduct medication reconciliation at hospital admission and discharge for all patients	Conduct medication reconciliation at all outpatient visits
Clinical pharmacists at the point of practice	Pharmacist joins inpatient team for daily rounds	Pharmacist is based in outpatient practice
Bar code systems	Nurse must swipe bar code on medication, patient's wristband, and nurse's identification badge before medication administration	A bar code system is used to match a patient's wristband with labels used for outpatient laboratory tests
Standardization and checklists	A preprocedure checklist is used to reduce catheter-related bloodstream infections	Nursing staff uses a checklist to maintain standardized examination room stocking of needed equipment and supplies
Standard communication and handoff procedures	The I-PASS (I: illness severity; P: patient summary; A: action items; S: situation awareness and contingency planning; S: synthesis by receiver) handoff bundle is used to promote safer inpatient care ( <a href="http://www.ipasshandoffstudy.com/about">www.ipasshandoffstudy.com/about</a> )	SBAR (situation, background, assessment, recommendations) is used to structure standard communication when sending a patient from the outpatient practice to the emergency department
Forcing functions	Intravenous pumps and gastrostomy tubing have different connectors to avoid errors	Prescription dosing on an electronic medical record is limited by the patient's weight to avoid underdosing and overdosing
Redundancy	Pharmacist and 2 nurses check medication dose before administration	Physician and nurse check vaccine order with immunization registry record before administration
Health information technology	An electronic order set is used to standardize management of inpatients with asthma exacerbations	Electronic prescriptions assist in reducing errors in medication orders filled by community pharmacies
Quality improvement methodology	A hospital-wide quality improvement collaborative was effective in reducing adverse drug reactions	An outpatient pediatric practice aims to improve informing parents about newborn screen results to a level of 90% within the next 6 months and uses plan-do-study-act cycles to achieve this aim
Education of staff and trainees	All inpatient pediatric staff are trained in the TeamSTEPPS process to improve communication and teamwork skills ( <a href="http://teamstepps.ahrq.gov">teamstepps.ahrq.gov</a> )	All pediatric practice staff are given training in medication reconciliation to reduce medication errors

Derived from McClead RE, Catt C, Davis JT, et al. An internal quality improvement collaborative significantly reduces hospital-wide medication error related adverse drug events. *J Pediatr*. 2014;165(6):1222–1229.

### BOX 288-2 Steps of Medication Reconciliation

1. Develop a list of current medications.
2. Develop a list of medications to be prescribed.
3. Compare the medications on the 2 lists.
4. Make clinical decisions based on the comparison.
5. Communicate the new list to appropriate caregivers and to the patient.

setting. Pharmacists trained in pediatric pharmacotherapy may promote safe and effective drug therapy for children and prevent harm from medication errors, particularly when these professionals are integrated into the medication prescription process from the beginning.

### Bar Code Systems

The implementation of a bar code medication administration system reduced preventable adverse drug events in an NICU by 47%. Bar code systems are also implemented to prevent errors in patient identification.

However, new errors may occur when workarounds are used, such as wearing patient bar-coded labels on nursing scrubs or affixing them to computer carts to avoid scanning the patient's identification wristband each time medication is administered.

### Standardization and Checklists

Preprinted order sets have led to reduced pediatric sedation errors. Other printed and computerized order sets may be of value in preventing medication errors. A checklist was effective in reducing the rate of technical prescription writing errors in a pediatric inpatient setting. The 19-item WHO Surgical Safety Checklist was developed to decrease errors and adverse events and increase teamwork and communication in surgery. It has been effective in reducing surgical morbidity and mortality and has been implemented internationally ([www.who.int/patientsafety/safesurgery/checklist/en](http://www.who.int/patientsafety/safesurgery/checklist/en)).

### Standard Communication and Handoff Procedures

Patient handoff communication errors are a major source of adverse events. A resident handoff bundle, including standardized communication and handoff training, a verbal mnemonic, and a new team hand-off structure, was effective in reducing handoff errors among hospitalized children.

### Forcing Functions

A forcing function is a limit built into a process that impels the user to take the correct action. It prevents a target action or allows it to occur only if another specific action happens first. An example of a forcing function is the removal of concentrated potassium from general inpatient units.

### Redundancy

Redundancy is duplication of the key part of a process to reduce the likelihood of error. An example is 2 nurses checking medication orders and preparation. These double-checking or backup systems may not ensure safety because they often rely on human behavior.

### Health Information Technology

Electronic prescribing has the potential to reduce outpatient medication errors, particularly if the program is incorporated into an electronic health record, with access to patient medication histories, allergies, and clinical decision support. In the pediatric inpatient setting, computerized physician order entry has reduced medication prescription errors but has variable effect on patient outcomes.

Computerized clinical decision support, either stand-alone or in combination with computerized physician order entry, has been associated with decreased adverse drug events and error rates, but its effect on patient outcomes is uncertain. Specific alerts for duplicate medications, drug interactions, and drug allergies have not shown consistent benefit. Dosing calculators and dose range alerts may lower dosage errors, but alerts are frequently overridden by providers. Evidence-based reminders may help promote better adherence to evidence-based clinical practice guidelines.

### BOX 288-3 Steps in Failure Modes and Effects Analysis

- Define steps in the process under study.
- Delineate potential failure modes (ie, What could go wrong?).
- Analyze causes of potential failure in the process.
- Describe consequences of each failure.

### Quality Improvement Methodology and Multidisciplinary Safety Teams

Quality improvement efforts involving multidisciplinary teams to detect errors and implement system changes may help us understand the factors contributing to pediatric medical errors and generate more effective strategies to prevent them. A continuous quality improvement approach with voluntary, nonpunitive error reporting systems, coupled with multidisciplinary teams to analyze reports and recommend rapid system changes, has been effective in addressing medical errors in the ambulatory setting. Reports of effective use of quality improvement methodology to reduce medical errors in the pediatric inpatient setting have been reported among general pediatric and neonatal patients, as well as in pediatric subspecialty units caring for children with cardiac, oncologic, and neurologic conditions.

One type of quality improvement methodology that is useful in addressing adverse events before they occur is *failure modes and effects analysis* (FMEA). This is used to proactively evaluate processes for possible failures and to prevent them rather than reacting to medical errors that have already occurred. FMEA is a systematic preventive quality improvement method to identify potential sources of failure of a process and to assess the relative effect of different failures, with the goal of identifying the steps in the process where changes would be effective in reducing the risk for errors (see Box 288-3). FMEA may be particularly useful in evaluating a new process before implementation and in assessing the effect of a proposed change to an existing process. FMEA has been used effectively to prevent medication errors in the pediatric inpatient setting.

### Educational Interventions

A physician prescribing tutorial may reduce prescription errors in the pediatric inpatient setting by 46%. Proper medication administration by NICU nurses may improve with a multifaceted educational program. Pediatric trainees may improve their prescription competency by ongoing training and monitoring and after participating in an e-learning program.

## Chapter 289 MENINGITIS

Geoffrey A. Weinberg, MD; Ann M. Buchanan, MD, MPH

The meninges of the central nervous system (CNS) include 3 membranes that support, protect, and nourish the brain and spinal cord. The outermost layer, the

dura mater, is a tough, inelastic, connective tissue layer that sheaths the brain and spinal cord and terminates caudally at the first coccygeal vertebra. The middle and innermost layers, the arachnoid and the pia mater, respectively, are similar in structure and are often referred to singly as the leptomeninges. The arachnoid and pia are partly separated, leaving a subarachnoid space containing cerebrospinal fluid (CSF). The CSF is formed in the choroid plexuses within the ventricles of the brain, which communicate with the subarachnoid space through the foramina of the fourth ventricle (via the median aperture of Magendie and the lateral apertures of Luschka). The CSF slowly circulates in both directions around the brain and spinal cord; it is reabsorbed predominantly by the arachnoid villi of the superior sagittal sinus.

Meningitis, or inflammation of the meninges, is most often caused by an infectious agent and less commonly by a chemical (medication) or malignancy. Bacterial meningitis, also known as *pyogenic meningitis*, is often quickly fatal, making early diagnosis and treatment essential.

Aseptic meningitis refers to inflammation of the meninges, as demonstrated by CSF pleocytosis, without the presence of visible micro-organisms on routine Gram staining and a negative culture for bacteria. Nonpolio enteroviruses cause 85% of cases of aseptic meningitis in the United States. However, fungi, parasites, reactions to medications, and atypical bacteria not well seen on Gram staining may also cause aseptic meningitis. Thus, the term is not synonymous with viral meningitis, although the 2 terms are often used interchangeably. The CSF findings characteristic of both pyogenic and aseptic meningitis are listed in Table 289-1 and Table 289-2. When encephalitis accompanies aseptic meningitis, the cause may be distinct, and the clinical course may be much more severe (see Chapter 290, Meningoencephalitis).

In partially treated meningitis, antibiotics have been provided before lumbar puncture is performed, rendering Gram staining and bacterial culture less useful (because of the possibility of temporary bacterial sterilization). Distinguishing partially treated bacterial meningitis with false-negative CSF cultures from aseptic meningitis can be difficult, although the accompanying CSF laboratory studies (white blood cell [WBC] count and differential, CSF protein, and glucose concentrations) may often be of assistance.

A number of reviews summarize in detail the epidemiology, pathophysiology, diagnosis, and treatment of meningitis in children and adults; this chapter highlights pertinent aspects of pediatric and neonatal meningitis.

### EPIDEMIOLOGIC FEATURES

The incidence of bacterial meningitis is related closely to age, and has been tremendously reduced overall in the past 20 years because of the implementation of routine bacterial polysaccharide-protein conjugate vaccinations. As an example, in the pre-conjugate vaccination era in the United States, as recently as the late 1980s, during the first month of life, the age-specific incidence was as high as 300 to 400 cases per 100,000 live births; cases of bacterial meningitis decreased to

141 per 100,000 during the second month of life and to less than 50 per 100,000 in the second year of life. A second peak occurred at 6 to 8 months, with an incidence of nearly 180 per 100,000 infants. This second peak, which was caused by *Haemophilus influenzae* type b (Hib) meningitis, has declined dramatically since 1988, when Hib conjugate vaccines were approved for use. Between 1987 and 1997, the incidence of Hib meningitis fell from 40 cases per 100,000 children younger than 5 years to 1 case per 100,000, and current annual estimates are as low as 0.1 cases per 100,000 (Figure 289-1). This remarkable decline in Hib meningitis converted bacterial meningitis to a disease predominantly of adults rather than of infants and young children, with the median age at diagnosis

25 years in 1995 as opposed to 15 months in 1985 (Figure 289-2).

With the implementation of routine immunization in the United States with pneumococcal conjugate vaccine in infancy in 2000, a 70% to 90% decline was documented in cases of invasive pneumococcal disease, including meningitis (Table 289-3). In 2009, a 13-valent pneumococcal conjugate vaccine replaced the 7-valent vaccine in the US immunization schedule, and the annual incidence rates of invasive pneumococcal disease in children ages 5 years or younger have fallen to approximately 20 per 100,000 children per year, as opposed to 100 per 100,000 children per year before routine conjugate vaccination began. Bivalent and tetravalent meningococcal conjugate

vaccines have been licensed for use in selected infants and children, and for general use in adolescents; similar monovalent and bivalent conjugate vaccines provided to infants and younger children have reduced meningococcal meningitis rates in Europe (see Table 289-3). In the United States, however, because the fraction of meningococcal disease in young children caused by the nonconjugate vaccine serogroup B is greater than that in Europe, use of the current tetravalent conjugate vaccine (serogroups ACYW135) will not eliminate meningococcal infection in infants.

**Figure 289-1** Incidence of *Haemophilus influenzae* type b meningitis per 100,000 children younger than 5 years of age in the United States, 1987-1997. (From Centers for Disease Control and Prevention. Progress toward eliminating *Haemophilus influenzae* type b disease among infants and children—United States, 1987-1997. MMWR Morb Mortal Wkly Rep. 1998;47(46):993.)

In addition to the age-related changes in incidence, the spectrum of etiologic agents of bacterial meningitis changed remarkably with age—at least before the routine implementation of antibiotic prophylaxis for group B  $\beta$ -hemolytic streptococci and the licensure of conjugate vaccines (Figure 289-3). Until recently, during the first month of life, more than two-thirds of the cases of neonatal bacterial meningitis were caused by group B  $\beta$ -hemolytic streptococci (*Streptococcus agalactiae*) or gram-negative enteric organisms, primarily *Escherichia coli*, *Klebsiella*, and *Enterobacter* species. With antibiotic prophylaxis, the contribution of group B  $\beta$ -hemolytic streptococci to early-onset meningitis is decreasing (although late-onset disease has not decreased). In some regions, another fairly common cause of neonatal meningitis is *Listeria monocytogenes*. After the first month of life, *Listeria* organisms are found as the cause of meningitis mostly in immunocompromised or elderly persons.

The incidence of aseptic meningitis (predominantly caused by enteroviruses) ranges, in different years, from 1.5 to 4 cases per 100,000 population. The incidence in children is actually much higher because aseptic meningitis is still a disease of the young, with few reported cases occurring in persons older than 30 years; however, age-adjusted incidence rates are not available.

## BACTERIAL MENINGITIS AFTER THE NEONATAL PERIOD

Most cases of bacterial meningitis in children older than 1 month are caused by *Neisseria meningitidis* or, increasingly less often, *Streptococcus pneumoniae* or Hib in regions where pneumococcal and Hib conjugate vaccines are widely used (Figure 289-3 and

**Figure 289-2** Incidence and median age of cases of bacterial meningitis in the USA during selected years 1986-2007, caused by *Listeria monocytogenes*, *Streptococcus agalactiae*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. **Figure 289-3** Proportions of 587 cases of pediatric bacterial meningitis in the USA in 2003–2007 caused by each pathogen, according to age group. GBS, group B *Streptococcus* (*Streptococcus agalactiae*). (From Thigpen MC, Whitney CG, Messonnier NE, et al. Bacterial meningitis in the United States, 1998–2007. *New Engl J Med* 2011;364(21):2016–2025. Used by permission.)

Table 289-3). Current mortality rates vary according to the pathogen and have been reported to be up to 10% for *S pneumoniae*, 4% for *N meningitidis*, and less than 1% for Hib.

All 3 of these pathogens can be isolated from the throat or nasopharynx of healthy individuals. Most studies of microorganism carrier states suggest that

children at highest risk for disease are also the most likely to be colonized. In the pre-Hib conjugate vaccine era, approximately 70% of toddlers and 48% of the preschool-aged children in some child care centers were colonized with Hib, but no invasive Hib disease was observed. Thus, colonization with Hib, *S pneumoniae*, or *N meningitidis*, does not always cause

meningitis. Indeed, nasopharyngeal colonization may be a partially immunizing event that contributes to future host defense; however, when microbial virulence factors overcome host defense, bacterial meningitis ensues.

The successful meningeal pathogen must follow several sequential steps. Nasopharyngeal mucosal colonization is facilitated by various microbial-binding adhesins and secreted enzymes such as immunoglobulin A (IgA) protease, which cleaves host secretory IgA. Next, invasion across the epithelium, followed by survival of bacteria in the bloodstream (by evading the action of the alternative complement pathway) are required. Finally, the bacteria must invade the CSF by crossing the blood-brain barrier.

Meningitis may occasionally occur after head trauma, particularly with fractures of the paranasal sinuses or middle ear. The pathogens most often associated with meningitis after trauma are *S pneumoniae* (often less pathogenic capsular serotypes) and *H influenzae* (often nontypable or encapsulated but non-type b strains). Post-traumatic meningitis can recur if CSF leakage persists.

Meningitis can also occur by direct spread from a congenital dermal sinus that communicates with the CNS. Any time meningitis is caused by bacteria that normally reside on the skin or in the gastrointestinal tract, a diligent search of the craniospinal axis should be made. Meningitis can develop after neurosurgery and is not uncommon after procedures performed to shunt ventricular fluid. Coagulase-negative staphylococci are the organisms most often associated with shunt infections. Cochlear implantation has been recognized as an additional risk factor for bacterial meningitis.

Once bacteria establish growth in the CSF, cell wall products, such as lipopolysaccharide (endotoxin), teichoic acid, and peptidoglycans, are liberated, which induce the local production and secretion of inflammatory cytokines (especially interleukin-1 and -6 and tumor necrosis factor). The action of these cytokines results in activation of leukocytes and vascular metabolism, which leads to leukocyte migration (diapedesis), endothelial injury, and blood-brain barrier breakdown. The injury to the cerebral microvasculature, along with increasing inflammation, culminate in brain edema, reduction of cerebral blood flow, thrombosis, and impairment of oxygen and glucose delivery.

### Differential Diagnosis

Signs and symptoms suggesting meningeal inflammation or increased intracranial pressure can arise from infections of the CNS other than pyogenic meningitis. The most common cause of meningeal inflammation is enteroviral aseptic meningitis, which is discussed later in this chapter. Aseptic meningitis can also be caused by Lyme disease spirochetes (*Borrelia burgdorferi*), *Mycobacterium tuberculosis*, fungi, parasites, or inflammatory conditions. Meningitis or meningoencephalitis may also be present in children who have Rocky Mountain spotted fever (see Chapter 325), Kawasaki disease (see Chapter 280), cat-scratch disease, or toxic shock syndrome (see Chapter 340), and is often associated with or occurs after mumps, rubeola, rubella, varicella, infectious mononucleosis, roseola, and erythema

infectiosum (Table 289-4). A brain abscess, epidural abscess, primary amebic meningoencephalitis, embolic diseases (eg, endocarditis, thrombophlebitis), venous sinus thrombosis, space-occupying lesions, reactions to medications (eg, intravenous immunoglobulin, intravenous monoclonal antilymphocyte antibody, oral trimethoprim-sulfamethoxazole, some oral nonsteroidal anti-inflammatory drugs), ingestion of toxins (eg, lead), spider bites, pemphigus, and Behçet syndrome can mimic bacterial meningitis. However, interpretation of the CSF findings in the context of the clinical manifestations usually differentiates bacterial meningitis from other diseases. Eosinophilic meningitis is rarely seen; the differential diagnosis includes reactions to ventriculoperitoneal shunts, unusual presentations of bacterial or *Toxoplasma* infection, or parasitic roundworms. Conditions that can simulate a clinical picture of meningitis, but that usually have normal CSF findings, include pharyngitis (see Chapter 311, Pharyngitis and Tonsillitis), retropharyngeal abscess (see Chapter 348, Airway Obstruction), cervical adenitis (see Chapter 175, Lymphadenopathy), cervical spine arthritis or osteomyelitis (see Chapter 304), pyelonephritis (see Chapter 294, Nephritis), pneumonia (see Chapter 315), torticollis (see Chapter 203), tetanus, and oculogyric crisis.

### Clinical Manifestations

Children who have bacterial meningitis usually have a fever; however, the absence of fever in a child who has signs of meningeal irritation does not preclude the diagnosis. Inflammation of the meninges can be characterized by irritability, anorexia, headache, nausea, vomiting, confusion, back pain, nuchal rigidity, and photophobia. Kernig and Brudzinski signs can be assessed during the physical examination to demonstrate meningeal inflammation (Figure 289-4). Kernig sign is elicited in the supine child by extending the leg at the knee while the hip is flexed at 90 degrees. When positive, this maneuver causes extensor spasm of the knee and pain in the hamstrings of a person who has meningitis when the lower leg is extended to approximately 135 degrees. Brudzinski sign is elicited by flexing the neck of a child in the supine position; in a positive test, the child will involuntarily flex the hips and knees. Stiffness of the neck is a sensitive (80%–98%) indicator of true bacterial meningitis in children, adolescents, and adults.

In a young infant, however, signs of meningeal inflammation can be minimal or absent. Thus, in children younger than 12 months, the absence of nuchal rigidity must not be used to exclude meningitis. Distinguishing nuchal rigidity from voluntary movement and guarding can also be difficult in a sick infant with irritability. In this case, the additional signs of lethargy, poor feeding, and restlessness may be helpful. Additionally, laying the infant near the edge of the examining table with the head supported by the examiner's hand, but gently extended off the edge of the table, may be useful. The natural tendency for the infant in this position will be to try to lift the head, at which time the examiner can feel whether nuchal rigidity, rather than voluntary guarding or noncooperation, is preventing flexion of the neck.

**Table 289-4** Selected Causes of Aseptic Meningitis<sup>a</sup>

<sup>a</sup>Common, uncommon, and rare refer to relative frequencies within each broad category of etiologic agents (eg, viruses, bacteria). Overall, enteroviruses cause at least 85% of the aseptic meningitis diagnosed in children in the United States, and arboviruses cause approximately 5%; all other causes combined account for the remaining 10% or less of cases.

The child with meningitis may also have signs of increased intracranial pressure, such as a headache or a bulging fontanelle. Papilledema is uncommon with bacterial meningitis, and when present, other causes should be sought; bacterial meningitis progresses so quickly that papilledema may not have time to develop. Cranial nerve involvement sometimes occurs with bacterial meningitis, and although it is often transient, it can be permanent. The auditory nerve most often is affected, causing deafness or disturbances of vestibular function. Blindness has been reported but is rare. Children may also have paralysis of extraocular or facial nerves.

The degree of CNS derangement observed in children with bacterial meningitis ranges from irritability to coma. As many as 15% of children who have bacterial meningitis are comatose or semicomatose at the time of hospitalization. This circumstance occurs more often with *S pneumoniae* or *N meningitidis* than with Hib. Seizures occur before or within 1 to 2 days after admission in approximately 30% of children. Focal neurologic signs, which are present in approximately 16% of the children, correlate with persistent abnormal neurologic and developmental examinations 1 year after discharge. The distinction between bacterial meningitis and infectious meningoencephalitis

may be difficult to make when the child with coma or seizures first presents.

Subdural effusions occur in approximately 50% of children who have bacterial meningitis, but they are seldom clinically significant. Therefore, unless focal neurologic signs or signs of increased intracranial pressure develop, the presence of such effusions need not be sought through the performance of subdural taps or computed tomographic (CT) scans. Infection of subdural effusions is extremely rare.

Arthralgia and myalgia often occur in children who have meningitis, particularly those who have meningococemia. Vasculitis can be seen in children who have any type of bacterial meningitis, but petechiae and purpura are more commonly associated with meningococcal disease. Children who have such rashes should be considered in imminent danger of developing septic shock and should be treated accordingly (see Chapter 366, Meningococemia).

### Laboratory Testing and Findings

When meningitis is suspected in a child who does not have papilledema, a lumbar puncture should be performed, the opening pressure measured, and the CSF examined immediately. The clinical situation should influence the amount of data required before a

#### Kernig Sign

When the hips are flexed at 90 degrees, attempting to extend the leg at the knee past 135 degrees causes pain and/or extensor spasm.

#### Brudzinski Sign

Flexion of the neck while laying supine causes involuntary hip and knee flexion.

**Figure 289-4** Kernig sign and Brudzinski sign, signs of meningitis at physical examination in addition to nuchal rigidity.

therapeutic decision is made. If the CSF from an ill, febrile child is turbid or purulent, then antimicrobial therapy should be initiated as treatment for bacterial meningitis before further laboratory results are available. In any case, the CSF should be examined as soon as possible. If the nucleated blood cell count of the CSF is not above 6/ $\mu$ L, then the only other tests likely to be useful in diagnosing bacterial meningitis are a Gram stain and a culture. However, most experts suggest that a Gram stain, bacterial culture, cell count, differential cell count, and CSF concentrations of total protein and glucose should be performed on CSF from all samples drawn by a lumbar puncture. If possible, the blood glucose should be measured just before the lumbar puncture is performed so that the ratio of CSF to blood glucose can be determined; measuring the blood glucose level before the lumbar puncture is best because the stress of the procedure can temporarily increase it. If only a small amount of CSF is obtained, then the most important tests to perform are a Gram stain and bacterial culture. Characteristic CSF findings are listed in Table 289-1. A useful review and Internet-accessible video on performing a lumbar puncture is available (see Tools for Practice). Refinements of the reference ranges for CSF opening pressure and chemical and cellular parameters (see Appendix C, Formulas and Reference Range Values)

continue to be published for young children and infants, as some differences from adult ranges are noted.

The CSF should be cultured on chocolate and blood agar plates and in broth. Generally, bacterial cultures will be positive within 2 days if pathogens are present. In some settings, the causative agent may also be identified by latex agglutination reactions, immunochromatographic reactions, or polymerase chain reaction (PCR) amplification of nucleic acids. Rapid diagnostic tests are likely to be most valuable in children who receive a significant amount of antibiotics 24 hours or more before a lumbar puncture, or in developing countries without microbiologic facilities. Blood cultures should be obtained for all children suspected of having bacterial meningitis; blood cultures are positive in 80% to 90% of children who did not previously receive antimicrobial agents and who have meningitis caused by Hib, *S pneumoniae*, or *N meningitidis*.

A common clinical concern is how to distinguish the CSF abnormalities caused by infection from those associated with a traumatic lumbar puncture. Common clinical practice is to use the ratio of red blood cells to WBCs to correct the observed CSF WBC count, either by subtraction or by examination of the ratio of observed to expected cells. Despite the apparently sound theoretical basis for these calculations, in practice, they are generally not helpful to the physician in deciding whether to proceed with antibiotic therapy, and bacterial or viral cultures will yield a more definitive answer relatively quickly.

Two additional common clinical concerns regard the need for a diagnostic lumbar puncture in young children experiencing a stereotypical febrile seizure and the timing of the lumbar puncture, including the need to perform cranial CT scans before the lumbar puncture.

Although seizures in febrile children were reported to be the first manifestation of bacterial meningitis in as many as 20% of children in the pre-conjugate vaccine era, most of the children were also obtunded or comatose at the time of presentation, distinguishing them from children with stereotypical febrile seizures. The large decrease in the incidence of bacterial meningitis in immunized children in the United States, combined with several studies of the nonutility of a lumbar puncture in children with typical febrile seizures in the absence of other symptoms or signs of meningitis have led the American Academy of Pediatrics to revise practice guidelines for neurodiagnostic evaluations in children with febrile seizures. For children 6 to 12 months of age thought to have a simple febrile seizure, a lumbar puncture is considered an optional procedure, and is most important for those with signs and symptoms of meningitis, those pretreated with antibiotics, or incomplete or unknown immunization histories. A lumbar puncture is no longer required for the evaluation of all children with febrile seizures. Conversely, the presence of seizures should not be used to explain abnormalities of the CSF; if found, the diagnosis of meningitis must be considered.

In general, lumbar puncture should be performed whenever the diagnosis of meningitis is known or

suspected. Four reasons for delaying a lumbar puncture exist: (1) clinically important cardiorespiratory compromise, most often observed in the neonate; (2) signs of significantly increased intracranial pressure (eg, retinal changes, altered pupillary responses, focal neurologic signs during the physical examination, or increased blood pressure with associated bradycardia and hyperpnea [Cushing triad]); (3) infection in the skin, soft tissues, or epidural area at the site of the lumbar puncture; or (4) suspicion or history of bleeding disorders (eg, hemophilia, severe thrombocytopenia). In these circumstances, blood cultures should be obtained, and antibiotics should be provided empirically without performing a lumbar puncture. In cases of suspected increased intracranial pressure, arrangements should be made for a neuroimaging study (eg, cranial CT scan with and without contrast enhancement) during or immediately after antibiotic administration, and if the imaging study suggests that it is safe to proceed, then the lumbar puncture may follow. However, performing CT scans routinely before a lumbar puncture is not necessary in children with suspected meningitis, even though all children with meningitis have some degree of increased intracranial pressure by virtue of the disease process.

Herniation of the brain on removal of a small amount of CSF is rare in children with meningitis, especially in infants with open fontanelles. Herniation associated with meningitis has also been observed before a lumbar puncture and in the presence of normal cranial CT scans. Nevertheless, a lumbar puncture should be performed cautiously if significantly increased intracranial pressure is suspected; obtaining CT scans before a lumbar puncture in selected children is reasonable, especially in children or adults with a history of immunosuppression, hydrocephalus, ventricular shunts, or head trauma, as well as in those who have focal neurologic signs or signs of greatly increased intracranial pressure.

If the lumbar puncture could not initially be performed or was contraindicated, then the procedure may be reconsidered after the child is stabilized and contraindications to the procedure are resolved. A lumbar puncture may be performed even 12 to 24 hours after initiating antimicrobial therapy. In this situation, the interpretation of CSF WBC counts and protein and glucose concentrations may still be helpful in discerning the likelihood of true bacterial meningitis.

## Management

### General Care

Antimicrobial therapy, fluid management, and possibly anti-inflammatory adjunctive treatments are crucial for all children who have bacterial meningitis. Even today, controversy remains about mechanisms of action, usefulness, and choice of these interventions.

At the initial examination, children who have meningitis may seem only mildly ill with fever and irritability, or they may be profoundly ill with an altered state of consciousness and hypotension. The severity of illness at the time the child is brought in for care can predict morbidity and should dictate immediate management. Acute bacterial meningitis is always a medical

emergency, and all infants and children who have an altered state of consciousness should be observed closely and the need for intensive care anticipated.

As soon as bacterial meningitis is diagnosed, intravenous access should be secured and appropriate antimicrobial agents (and possibly anti-inflammatory agents) provided. The initial laboratory examination should include CSF examination and culture, blood culture, measurement of serum electrolyte and glucose concentrations, complete blood and platelet count, and measurement of urine specific gravity. If the child has petechiae or purpura or is in shock, then the laboratory tests should include a partial thromboplastin time, prothrombin time, and measurement of fibrinogen- or fibrin-breakdown products. Management of the child who is awake and has stable cardiorespiratory vital signs consists primarily of administering antimicrobial agents and fluids and careful monitoring for changes in level of consciousness, development of seizures, changes in vital signs, and development of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Other therapies should be considered in more critically ill children (see the discussion of management of septic shock in Chapter 373, Shock). Seizures should be treated with appropriate anticonvulsants. An open airway that provides good oxygenation should be ensured. Children who are in a profound coma or whose level of consciousness deteriorates while receiving therapy should be evaluated for complications such as a cerebral abscess, obstructive hydrocephalus, or high intracranial pressure. A CT scan of the brain with and without contrast is helpful in determining the diagnosis in such cases.

Radiographs may help in identifying suspected bone or joint infection in selected children. CT studies play a role in complicated cases of meningitis and may be helpful for decisions on management later during the course of therapy, as well as, for example, evaluating selected cases of prolonged (primary) or recurrent (secondary) fever. However, CT scans should not be routinely obtained as a result of prolonged or secondary fever because such scans are unlikely to affect clinical management. If high intracranial pressure is a major clinical concern and treatment has been initiated or is anticipated, then a neurosurgeon should be consulted and an intracranial pressure monitoring device placed, although, notably, all children with bacterial meningitis have some increase in intracranial pressure, and monitoring devices are not required for most.

### Fluid Therapy

Traditionally, fluids were restricted to two-thirds of the total daily maintenance amount in children who had bacterial meningitis to minimize brain edema and prevent SIADH, which was reported to occur in 29% to 88% of cases of bacterial meningitis. However, some studies found that plasma antidiuretic hormone concentrations return to normal in children with bacterial meningitis who receive replacement plus maintenance fluids for 24 hours, whereas concentrations remain high in children restricted to two-thirds of maintenance requirements.

How should the physician interpret these contradictory data? Dehydration likely produces an appropriate increase of antidiuretic hormone, but SIADH may still occur in nondehydrated or fluid-replete children. Maintenance fluids are likely necessary to perfuse, oxygenate, and deliver host defenses to the CNS, and although SIADH occurs in bacterial meningitis, no firm evidence has been found that fluid restriction prevents it. Obvious fluid deficits should be rapidly corrected, and serum sodium concentrations should be closely monitored several times during the first 24 hours of therapy, along with measurements of urine specific gravity. If the serum sodium concentration drops below 125 mEq/L, then the test should be repeated as soon as possible. If the serum sodium is still below 125 mEq/L, then fluids should be restricted to keep the vein open until the serum electrolyte concentrations are corrected. Otherwise, for the child with bacterial meningitis, providing routine maintenance fluids (such as 0.45% saline with added potassium and dextrose) at approximately 80% of the maintenance rate after fluid repletion and advancing to full maintenance rates as the serum sodium increases beyond 135 mEq/L seems to be appropriate. The period of fluid restriction likely only needs to be 1 day or less.

### Anti-inflammatory Therapy

The use of glucocorticoids as adjunctive therapy in children who have bacterial meningitis has been studied for decades yet continues to be controversial. Glucocorticoids and other anti-inflammatory compounds produce definite salutary changes in experimental meningitis models that ought to imply better outcomes for children. However, such therapy may also cause gastrointestinal bleeding, decreased penetration of antimicrobial agents into the CSF, and obfuscation of the clinical assessment of children's response to therapy. In addition, there seem to be differences in benefit in studies of adults as opposed to children, and in the industrialized world as opposed to the developing world. At present, it can be said that dexamethasone likely improves the hearing outcomes of children in the industrialized world who have bacterial meningitis caused by Hib, but its usefulness in non-Hib meningitis remains unproven. In addition, dexamethasone does not seem to benefit children or adults with bacterial meningitis in developing nations. In some studies of adults in industrialized countries with meningitis caused by *S pneumoniae*, decreased neurologic morbidity and mortality has been reported. In summary, at present in the United States, dexamethasone should be administered before or within 1 hour of the first dose of antimicrobial agents to children 6 weeks of age or older who have Hib meningitis, and considered for children who have pneumococcal meningitis; it has no role in cases of neonatal meningitis or aseptic meningitis.

### Antimicrobial Therapy

Knowing the causative agent at the time of diagnosis of bacterial meningitis is difficult. Empirical guides to therapy are primarily based on age, which predicts the most likely cause. Adjustments to therapy can be made as conjugate vaccination history and results of the CSF Gram stain and culture are confirmed

(Table 289-5). However, organism-specific points regarding therapy are noted below.

Until the early 1990s, most *S pneumoniae* strains were susceptible to penicillin or ampicillin and the third-generation cephalosporins—ceftriaxone and cefotaxime. Since then, numerous reports have been issued of infections in infants and children caused by resistant strains of pneumococci. Up to 40% of pneumococcal isolates may be resistant to penicillin at some level, and some also are resistant to the third-generation cephalosporins. Therefore, infants and children suspected of having bacterial meningitis caused by pneumococci (ie, gram-positive cocci in pairs seen on a Gram stain of the CSF) should receive vancomycin in addition to either ceftriaxone or cefotaxime. Because dexamethasone can decrease the CSF penetrance (and thus the activity) of vancomycin, some experts advise that either dexamethasone should be omitted altogether or rifampin plus vancomycin plus a third-generation cephalosporin should be used when dexamethasone is provided. As soon as the antimicrobial susceptibility of an isolate is known, vancomycin should be discontinued if the isolate is susceptible to penicillin or if it is nonsusceptible to penicillin but still susceptible to the third-generation cephalosporins. Vancomycin is continued with ceftriaxone or cefotaxime for those isolates found nonsusceptible to both penicillin and the third-generation cephalosporins (and rifampin is added to the combination in some circumstances) (Table 289-4). Consultation with an infectious diseases subspecialist is suggested.

In areas with a low prevalence of penicillin-nonsusceptible pneumococci, especially when examination of the CSF Gram stain shows the absence of gram-positive cocci, providing a third-generation cephalosporin alone (without vancomycin) for empiric therapy is reasonable. Suspected or proven Hib disease may be treated reliably with either ceftriaxone or cefotaxime; ampicillin may be used only if the isolate is known to be susceptible. Disease caused by *N meningitidis* is treated reliably with penicillin G at high doses or alternatively by ampicillin or a third-generation cephalosporin (Table 289-4).

Meningitis caused by *N meningitidis* is usually treated for 7 days, that caused by Hib for 10 days, and that caused by *S pneumoniae* for 10 to 14 days, although a 7-day course of antimicrobial therapy for uncomplicated Hib and *S pneumoniae* meningitis may be effective. Chloramphenicol is now rarely used for therapy in the industrialized world; if an alternative agent beyond ampicillin or third-generation cephalosporins is required, then meropenem may be administered; consultation with an infectious diseases specialist is suggested. Although these 3 organisms cause most cases of bacterial meningitis beyond the neonatal period, other bacteria can cause meningitis. In such cases, antimicrobial therapy must be individualized.

Most therapeutic failures can be related to inadequate therapy with the correct antimicrobial agent, resistant organisms, or a long delay in diagnosis. A repeat lumbar puncture performed after therapy is completed does not reflect the adequacy of therapy or predict the

**Table 289-5** Antimicrobial Therapy of Bacterial Meningitis**PART A. EMPIRICAL THERAPY PENDING CULTURE AND SUSCEPTIBILITY DATA**

AGE	LIKELY PATHOGENS	ANTIMICROBIAL AGENT
0–1 mo	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i>	Ampicillin + cefotaxime or ampicillin + aminoglycoside
1–3 mo	<i>S agalactiae</i> , <i>L monocytogenes</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> b	Ampicillin + (cefotaxime or ceftriaxone) <i>plus</i> vancomycin (see text)
3 mo–21 yr	<i>S pneumoniae</i> , <i>N meningitidis</i> ( <i>H influenzae</i> b if not vaccinated)	(Ceftriaxone or cefotaxime) <i>plus</i> vancomycin (see text)

**PART B. SPECIFIC THERAPY**

PATHOGEN	THERAPY
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G for 14–21 days; first 3 days, add gentamicin; cefotaxime also acceptable
<i>Listeria monocytogenes</i>	Ampicillin for 14–21 days; first 3 days, add gentamicin
<i>Streptococcus pneumoniae</i>	Penicillin MIC $\leq 0.06$ $\mu\text{g/mL}$ and ceftriaxone or cefotaxime MIC $\leq 0.5$ $\mu\text{g/mL}$ : penicillin G or ampicillin for 10–14 days; ceftriaxone or cefotaxime also acceptable Penicillin MIC $\geq 0.12$ $\mu\text{g/mL}$ and ceftriaxone or cefotaxime MIC $\leq 0.5$ $\mu\text{g/mL}$ : ceftriaxone or cefotaxime for 10–14 days Penicillin MIC $\geq 0.12$ $\mu\text{g/mL}$ and ceftriaxone or cefotaxime MIC $\geq 1.0$ $\mu\text{g/mL}$ : (ceftriaxone or cefotaxime) + vancomycin $\pm$ rifampin for 10–14 days
<i>Neisseria meningitidis</i>	Penicillin G for 7 days; alternatives: ampicillin, ceftriaxone, cefotaxime
<i>Haemophilus influenzae</i> b	Ceftriaxone or cefotaxime for 10 days; alternative: ampicillin if isolate is susceptible

**PART C. ANTIMICROBIAL DOSAGE**

AGENT	DOSE (mg/kg/day)		
	AGE 0–7 DAYS	AGE 8–28 DAYS	INFANTS AND CHILDREN
Ampicillin	150–200 divided every 8 hr	200–300 divided every 6 hr	200–300 divided every 6 hr
Cefotaxime	100 divided every 12 hr	200 divided every 8 hr	200–300 divided every 6 hr
Ceftriaxone	Not recommended	80–100 divided every 12–24 hr	80–100 divided every 12–24 hr
Gentamicin	5 divided every 12 hr	7.5 divided every 8 hr	7.5 divided every 8 hr
Penicillin G	100,000–150,000 units divided every 12 hr	150,000–200,000 units divided every 6 hr	300,000–400,000 units divided every 4–6 hr
Rifampin	10 divided every 12 hr	20 divided every 12 hr	20 divided every 12 hr
Vancomycin	20 divided every 12 hr	30 divided every 8 hr	40–60 divided every 6 hr

MIC, minimum inhibitory concentration.

likelihood of recurrence, and such a procedure is usually not indicated. However, a delay in sterilizing the CSF beyond 24 to 36 hours has been associated with adverse outcomes; therefore, another lumbar puncture may be performed at that time. A repeat lumbar puncture at 24 to 48 hours of therapy should be considered if drug-resistant *S pneumoniae* is present, especially if dexamethasone therapy is provided.

Some contacts of patients who have *N meningitidis* or Hib meningitis are at increased risk for the disease and should therefore receive prophylaxis. Prophylactic regimens for those at risk for *N meningitidis* are described in Chapter 366, Meningococcemia. Whether all contacts of children who have Hib disease should receive prophylaxis remains controversial. The American Academy of Pediatrics recommends that rifampin

be provided to all household contacts, including adults, in households that have at least 1 contact younger than 4 years whose immunization status against Hib is incomplete. The definition of complete immunization depends on the age of the individual involved, and that of household contact on how much time has been spent close to the index patient. The index patient should also receive rifampin either during or at the completion of treatment for Hib or meningococcal meningitis, unless ceftriaxone or cefotaxime was used for treatment (ceftriaxone and cefotaxime clear meningococcal and Hib carriage).

**Complications**

Early in the course of bacterial meningitis, increased intracranial pressure, septic shock, disseminated

intravascular coagulation, and even cardiorespiratory arrest may occur. Subdural effusions occasionally cause seizures or focal neurologic deficits; in such cases, the fluid should be removed by subdural taps. Such effusions are rarely infected directly, but subdural empyemas are occasionally reported. Syndrome of inappropriate secretion of antidiuretic hormone can also complicate bacterial meningitis; thus, the child should be monitored carefully for this complication. If it occurs, fluid should be sharply restricted. A brain abscess is extremely rare after bacterial meningitis except in neonates who have meningitis caused by *Citrobacter* or certain *Cronobacter* (formerly *Enterobacter*) species.

### Sequelae

Despite the appropriate use of bactericidal antibiotics, the mortality rate for bacterial meningitis remains at 5% to 10%. Approximately 15% to 25% of survivors have long-term morbidity, including developmental delay and lower educational achievement, seizure disorder, spasticity, and hearing loss.

Predicting long-term sequelae for an individual child is difficult at the time of discharge from the hospital. Some children who are apparently normal are later found to have hearing or learning deficits or a seizure disorder. Conversely, some children expected to have a dismal prognosis based on abnormal neurologic examinations at discharge make remarkable gains. The physician should therefore be guardedly optimistic with the family while remaining sensitive to possible sequelae and observing these children closely for attainment of developmental milestones. Hearing should be tested formally before discharge from the hospital because most sensorineural hearing loss can be detected at this time. The rate of persistent bilateral or unilateral sensorineural hearing loss is 31% after pneumococcal meningitis, 10.5% after meningococcal meningitis, and 6% after Hib meningitis. In young infants, auditory brainstem response or otoacoustic emissions testing is necessary for screening; in older toddlers and children, conditioned response, play, or conventional audiometry may be performed.

Current thinking asserts that much of the hearing loss in meningitis occurs soon after infection. This circumstance may explain why not all studies have shown a reduction of hearing loss by dexamethasone therapy. The timing of other neurologic sequelae is even less certain. Some cases of bacterial meningitis exhibit fulminantly, and the outcome in these cases may be poor no matter how quickly therapy is rendered. In many cases, the exact onset of disease is difficult to pinpoint, and the length of prodromal symptoms before therapy does not correlate well with outcomes.

### Prevention

In 1985 a purified capsular polysaccharide vaccine against Hib was licensed for use in the United States in children older than 2 years (in whom the risk of Hib disease was, albeit, substantially lower than that of the highest-risk group, infants younger than 1 year). Subsequently, several conjugate vaccines were made by coupling the Hib capsular polysaccharide to various

protein carriers to boost immunogenicity in infants. These conjugate vaccines were also more immunogenic in older children with conditions associated with impaired responses to capsular polysaccharide vaccine. As noted in Epidemiologic Features, the widespread use of Hib and pneumococcal conjugate vaccines dramatically reduced the incidence of invasive Hib and pneumococcal infection. Similar changes have been noted in the United Kingdom with meningococcal serogroup C conjugates (see Table 289-3).

One of 3 Hib conjugate vaccines or 1 of 3 Hib conjugate-containing combination vaccine products is routinely provided to US infants beginning at 2 months of age. Pneumococcal conjugate vaccine (13-valent) is recommended for routine universal administration to infants and children younger than 2 years of age, in a similar fashion to Hib conjugate vaccines. The pneumococcal conjugate vaccine is also suggested for high-risk children 2 to 5 years of age, including children who have sickle cell disease, functional or anatomic asplenia, immunosuppression, cancer, chronic renal disease, chronic cardiopulmonary disease, CSF leaks, and diabetes.

At present, 1 of 2 tetravalent meningococcal polysaccharide conjugate vaccines is routinely used for children and adults at higher risk of disease, as well as for young adolescents 11 to 12 years of age (with a booster dose in late adolescence). Meningococcal conjugate vaccines (tetravalent or bivalent) are also used for selected young infants and children at higher risk of disease, and as an adjunct to chemoprophylaxis in outbreak control. Two new meningococcal serogroup B vaccines were licensed for use in the United States in early 2015; recommendations for their use were forthcoming at the time this chapter was prepared (for more detailed information, see Chapter 20, Immunizations; Chapter 315, Pneumonia; and Chapter 366, Meningococcemia.)

### NEONATAL MENINGITIS

Neonatal meningitis merits separate consideration because the incidence is high, the agents that cause it are unique, and it is more often fatal than meningitis in the older child. The incidence of neonatal meningitis varies with the reporting institution, from 0.2 to 1 case per 1,000 live births. The age-specific incidence of bacterial meningitis in the first month of life in the United States between 1978 and 1981 was 366 per 100,000 neonates. Case fatality rates generally range from 5% to 25% in the modern era. In general, mortality is lower for full-term infants than for infants of low birth weight (<2,500 g). Early recognition and treatment are critical because the case fatality rate falls to approximately 5% for neonates who survive the first 24 hours of the disease.

The cause of neonatal meningitis has changed since 1970, and physicians should be alert to the possibility of future shifts. During the 1960s, most cases were caused by gram-negative enteric organisms, primarily *E coli*; gram-positive isolates were likely to be *L monocytogenes*. During the 1970s, group B  $\beta$ -hemolytic streptococci (*S agalactiae*) became prevalent; currently this organism and *E coli* account for 50% to 66% of cases of neonatal meningitis and *L monocytogenes* for

approximately 1% to 5%. Neonatal sepsis and meningitis caused by non-group D  $\alpha$ -hemolytic streptococci and coagulase-negative staphylococci also have been reported. Group B  $\beta$ -hemolytic streptococci can cause sepsis or meningitis (or both) in the first hours of life, and infections in infants younger than 7 days is termed early onset. Late-onset disease—that is, group B  $\beta$ -hemolytic streptococcal infections in infants older than 7 days—is characteristically meningitis rather than sepsis and tends to be associated with capsular serotype III organisms. Antimicrobial prophylaxis of pregnant women found to be carrying group B  $\beta$ -hemolytic streptococci at term, or those with fever, premature labor, or prolonged rupture of membranes, is now performed in the United States, which has led to a decrease in the incidence of early-onset sepsis and meningitis. However, late-onset meningitis rates remain unchanged, reflecting unique differences between these syndromes that remain unclear.

The clinical signs associated with neonatal meningitis are nonspecific and therefore not very helpful. Neonates with meningitis often have apneic episodes or feed poorly, and they can be hyperthermic or hypothermic, irritable or lethargic, and have respiratory distress or diarrhea (or both); only rarely do they have nuchal rigidity. They may exhibit a bulging fontanelle. The neonate has a limited repertoire of clinical responses to disease or insult. Therefore, most sick neonates receive a diagnostic evaluation for sepsis, including a lumbar puncture; antimicrobial agents are initiated pending culture results. The cytology and chemistry of the CSF in neonates have a much broader normal range than those of children in other age groups, especially during the first week of life (Table 289-2); thus, any single test result may not look abnormal. However, infants who have bacterial meningitis rarely have completely normal CSF at examination. During the first 24 hours of life, isolated meningitis without sepsis occurs rarely enough that a lumbar puncture has sometimes been omitted for infants who seem septic on the day of birth. However, this practice may lead to missed cases of both early-onset and late-onset meningitis because as many as 25% of neonates with meningitis have been found to have sterile blood cultures despite positive CSF cultures, and the proportion of such cases might rise as antibiotic prophylaxis is given to mothers and babies in the peripartum period. In general, if possible, any infant thought to have sepsis or meningitis should undergo a lumbar puncture.

### Management of Neonatal Meningitis

#### Antimicrobial Therapy

The principles of antimicrobial therapy for neonates with meningitis are the same as for infants and children, but because the organisms are different, the antimicrobial selection must be adjusted. Based on the most common organisms that cause neonatal meningitis, the ideal antimicrobial agent is effective against *E coli* and other enteric organisms and against group B  $\beta$ -hemolytic streptococci and other gram-positive organisms. Two third-generation cephalosporins—cefotaxime and ceftriaxone—are extremely active against the organisms that usually cause neonatal meningitis, except for

poor activity against *L monocytogenes*. The major difference between these drugs is their pharmacokinetic profile. Ceftriaxone exhibits a much longer serum half-life than cefotaxime. In addition, because ceftriaxone is highly protein bound and can displace unconjugated bilirubin from albumin, it is generally not used in premature infants at risk for kernicterus or in those young infants who have hyperbilirubinemia and for whom no other suitable antimicrobial agent is available with which to treat their infection.

No formal comparison of these newer agents with the historical regimen of ampicillin plus an aminoglycoside such as gentamicin has taken place. However, because the third-generation cephalosporins are safe, are very active against the common pathogens, and enter the CSF relatively well, cefotaxime plus ampicillin (the latter to empirically treat *Listeria*) should be used to treat suspected neonatal meningitis (suspected disease plus abnormal CSF). Some authorities add gentamicin as a third agent if gram-negative enteric meningitis is thought likely. Because some enteric pathogens such as *Pseudomonas aeruginosa* and Enterobacteriaceae readily become resistant to the third-generation cephalosporins, these antibiotics should not be used empirically for all cases of suspected sepsis in neonates (the choice of empiric ampicillin with gentamicin remains appropriate in this situation when the CSF seems normal). Dosages and characteristics of the antimicrobials used most often to treat neonatal meningitis are listed in Table 289-5.

#### Fluid Therapy, Anti-inflammatory Therapy, and Supportive Care

The role of intraventricular antimicrobial therapy remains uncertain and may even be harmful. Other therapeutic considerations (eg, fluid management, close serial monitoring) are the same for neonates as for infants and children who have bacterial meningitis, except that no data support the use of dexamethasone in infants younger than 6 weeks. The head circumference should be measured serially to detect early signs of hydrocephalus. Conflicting data have been reported regarding whether intravenous immunoglobulin is helpful. At present, it does not have a defined role in the therapy of neonatal bacterial meningitis.

#### Prognosis

The complications of neonatal meningitis, which are similar to those seen in older infants but are perhaps more common, include hydrocephalus, deafness, and blindness. The case fatality rate ranges from 5% to 25%. Approximately 65% of survivors of coliform meningitis are normal 3 to 7 years after the illness, approximately 15% to 30% have mild to moderate neurologic sequelae, and 5% to 10% have major sequelae. Approximately 55% of cases of group B  $\beta$ -hemolytic streptococcal meningitis survivors are normal, 25% have mild to moderate sequelae, and 20% have major sequelae (ie, blindness, bilateral sensorineural hearing loss, cerebral palsy, or profound developmental delay).

For unknown reasons, as many as 80% of neonates who have gram-negative enteric meningitis caused by either *Citrobacter* or certain *Cronobacter* (formerly *Enterobacter*) species will develop single or multiple

brain abscesses. This complication is distinctly unusual in meningitis caused by any other organism. Routine follow-up with cranial CT scans is indicated for neonates with meningitis or sepsis caused by *Citrobacter* species or *Cronobacter* (formerly *Enterobacter*) *sakazakii*.

As with older infants and children, all infants recovering from meningitis should have careful audiologic testing and close evaluation for attainment of developmental milestones.

### PARTIALLY TREATED MENINGITIS

Values for WBC counts in CSF, percentage of polymorphonuclear cells, and glucose and protein concentrations in children who have partially treated bacterial meningitis do not greatly differ from those in children who were not previously treated. Even children who received intravenous antibiotics for 44 to 68 hours have CSF findings characteristic of bacterial meningitis. Cultures of CSF from pretreated children with bacterial meningitis often grow Hib, although pneumococci and meningococci grow less often after pretreatment. However, some children who have partially treated bacterial meningitis have CSF findings indistinguishable from the classic findings of aseptic meningitis. Unless clear evidence of a nonbacterial cause exists (eg, identification of viral nucleic acid by PCR or isolation of virus by culture from CSF or blood), antibiotics should be administered to partially treated children for 7 to 10 days at doses appropriate for bacterial meningitis.

### ASEPTIC MENINGITIS

The syndrome of aseptic meningitis consists of a clinical picture of meningitis with CSF pleocytosis and the absence of bacteria on Gram stain or culture. The CSF findings characteristic of aseptic meningitis are shown in Table 289-1. Although aseptic meningitis is usually caused by a virus, treatable causes of this syndrome should be considered in the differential diagnosis. Table 289-4 lists a wide variety of infectious and noninfectious agents and diseases that are associated with aseptic meningitis. Nonpolio enteroviruses cause 85% of cases of aseptic meningitis in the United States, but mumps and polio should be considered in other areas of the world where they are still endemic. A longer duration of symptoms, especially if accompanied by erythema migrans or cranial neuropathies, has been associated with Lyme disease meningitis. West Nile virus infection may cause aseptic meningitis, meningoencephalitis, or acute flaccid paralysis. In general, when encephalitis accompanies aseptic meningitis, the clinical course is more severe, and the chance of sequelae increases (see Chapter 290, Meningoencephalitis).

### Clinical Manifestations

Infants and children who have aseptic meningitis caused by enteroviruses are often acutely febrile, irritable, and lethargic. Their temperature is usually 100.4°F to 105°F (38.0°C to 40.5°C) for 4 to 5 days. Upper respiratory tract symptoms, headache, photophobia, nausea, and vomiting also are commonly present; rashes may be seen as well. In general, a child who has viral meningitis does not seem as critically ill as a child

who has bacterial meningitis and is less likely to have meningeal signs.

The diagnosis of aseptic meningitis is likely when CSF pleocytosis ranges from 10 to 500 cells/ $\mu$ L that are predominantly lymphocytes; the CSF protein is mildly high at 50 to 150 mg/dL; and the CSF glucose concentration is normal. Early in the course of viral meningitis, polymorphonuclear neutrophils can predominate in the CSF. A transition from a predominance of polymorphonuclear neutrophils to lymphocytes usually occurs rapidly, and a repeat lumbar puncture after 8 to 12 hours may show this transition. Tuberculous and fungal meningitis generally have gradual onsets of illness over days to weeks.

Hypoglycorrhachia (low CSF glucose level) rarely occurs with viral meningitis caused by enteroviruses, mumps, herpes simplex, and Eastern equine encephalitis viruses. Hypoglycorrhachia caused by these viruses tends to result in CSF glucose concentrations that equal approximately 30% of the simultaneous blood glucose concentration, whereas bacterial meningitis usually results in CSF glucose concentrations of less than 30% of the blood glucose. The CSF glucose concentration can also be low with tuberculous and fungal meningitis.

Laboratory-confirmed enteroviral meningitis often results in discontinuation of antimicrobial therapy and early discharge from the hospital. For a long time, many physicians were reluctant to obtain specimens for viral culture because they thought that isolating viruses took too long to affect patient management, although enteroviruses may be detected by culture in as little as 4 days. The PCR amplification of viral nucleic acid in CSF has rectified the situation in many hospital laboratories, because PCR is a rapid, sensitive, and specific method of diagnosing meningitis caused by enteroviruses (and herpesviruses, among others). Children with aseptic meningitis should have CSF sent for both bacterial culture and enteroviral PCR, in an attempt to maximize diagnosis and shorten the length of antibiotic therapy in what may be viral meningitis.

### Management

The management of aseptic meningitis is directed mainly to supportive care. No specific anti-enteroviral agents are currently available. Meningoencephalitis caused by herpes simplex or varicella-zoster viruses should be treated with acyclovir. Aseptic meningitis caused by one of the other, less common causes noted in Table 289-4 (eg, Lyme disease) may also require specific therapy.

### Outcome

The outcome of aseptic meningitis relates to both the causative agent and the child's age. Most children with the most common known cause of viral meningitis—enteroviral meningitis—usually recover completely, although rarely some very young infants have been reported to suffer lower intelligence and delayed speech development. In light of these findings, the prognosis for an infant younger than 3 months with aseptic meningitis is more guarded than that of an older child, and the infant's development should be monitored carefully.

## FUNGAL MENINGITIS

Fungal meningitis generally has a more insidious onset than bacterial or viral meningitis, although the nature of clinical manifestations varies with the species of infecting organism. Rare in healthy children, fungal meningitis is most often diagnosed in hosts with some form of immunocompromise (eg, that caused by *Candida albicans* in premature infants or *Cryptococcus neoformans* in older adolescents with advanced HIV infection). However, fungal meningitis from endemic mycoses in the United States, such as *Histoplasma capsulatum* in the Ohio and Mississippi river valleys, *Coccidioides immitis* in Arizona and California, and *Blastomyces dermatitidis* in the upper Midwest and Northeast along the Great Lakes and the St Lawrence river, is seen in both infants and older children. Unusual fungal infections associated with injections of contaminated pharmaceuticals have been reported in adults, but not children, to date. Treatment of fungal meningitis varies according to the organism, and infectious diseases consultation is advised.

## TUBERCULOUS MENINGITIS

Meningitis caused by *Mycobacterium tuberculosis* is the most severe complication of tuberculosis (TB) in infants and children. Most cases occur within the first 5 years of life. In contrast to bacterial meningitis, TB meningitis often has an insidious onset, with nonspecific symptoms for more than 1 week, including fever, vomiting, malaise, poor weight gain or weight loss, and decreased mentation. The CSF profile tends to show a lymphocytic pleocytosis, with a low glucose level and a moderate to markedly high protein level (Table 289-1). The Mantoux skin test was positive in 60% of children with TB meningitis in a large South African study; it is possible that it might be positive more often in areas with fewer nutritional deficits. Tuberculosis of the CNS most often presents as basilar meningitis, but parenchymal tuberculomas and hydrocephalus may also be seen. Treatment of TB meningitis depends in part on the rates of local drug resistance among *M tuberculosis* isolates; for drug-susceptible strains, treatment includes 2 months of isoniazid, rifampin, pyrazinamide, and ethambutol (or ethionamide) once daily, followed by 7 to 10 months of isoniazid and rifampin, either once daily or twice per week, for a total treatment duration of 9 to 12 months. Although evidence for corticosteroid use in TB meningitis in young children is lacking, in older adolescents and adults dexamethasone or prednisone adjunctive treatment for several weeks seems to decrease mortality, although not necessarily morbidity.

### WHEN TO REFER

- All children with bacterial, fungal, or TB meningitis should be treated in consultation with pediatric infectious diseases subspecialists, and pediatric neurologic, critical care, and neurosurgical subspecialists should be available if required.
- Children with viral meningitis in whom unusual features or complications are present (eg, immune

compromise, unexpected severity, slow resolution of illness, possibility of nonviral aseptic meningitis, etc.) should be referred to pediatric infectious diseases and neurology specialists.

- Children with neonatal meningitis should be referred to pediatric infectious diseases, newborn medicine, and neurologic subspecialists.

### WHEN TO ADMIT

All children with suspected or proven meningitis should be hospitalized for evaluation and management.

- Children with bacterial, fungal, or tuberculous meningitis initially hospitalized at the referral hospital should be transferred to a facility experienced in the management of critically ill children, with availability of consultation by pediatric critical care, infectious diseases, neurologic, and neurosurgical subspecialists, which is especially important for newborns with neonatal meningitis. However, treatment must begin at the referral hospital.
- Infants and toddlers with viral meningitis may continue to be hospitalized at the primary care level hospital; transfer to a referral facility may be required for complicated cases (eg, uncertainty in diagnosis, slow resolution, presence of immune compromise, etc.).
- Older children and adolescents with viral meningitis do not always require hospitalization if the CSF evaluation strongly suggests that bacterial disease is not present, provided that adequate hydration and pain control can be undertaken at home and follow-up with the physician can be assured.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *Meningitis* (fact sheet), American Academy of Pediatrics ([www.healthychildren.org/English/health-issues/conditions/head-neck-nervous-system/pages/Meningitis.aspx](http://www.healthychildren.org/English/health-issues/conditions/head-neck-nervous-system/pages/Meningitis.aspx))
- *Meningitis* (fact sheets), Centers for Disease Control and Prevention ([www.cdc.gov/meningitis/index.html](http://www.cdc.gov/meningitis/index.html))

### Medical Decision Support

- *Lumbar Puncture* (video), Ellenby MS et al, *New England Journal of Medicine* Vol 355, Issue 13, 2006 ([www.nejm.org/doi/full/10.1056/NEJMvcm054952](http://www.nejm.org/doi/full/10.1056/NEJMvcm054952))
- *Meningitis: Resources for Healthcare Professionals* (Web page), Centers for Disease Control and Prevention ([www.cdc.gov/meningitis/clinical-resources.html](http://www.cdc.gov/meningitis/clinical-resources.html))

## AAP POLICY

American Academy of Pediatrics Subcommittee on Febrile Seizures. Febrile seizures: guideline for the neurodiagnostic evaluation of the child with a simple febrile seizure. *Pediatrics*. 2011;127(2):389–394 ([pediatrics.aapublications.org/content/127/2/389](http://pediatrics.aapublications.org/content/127/2/389))

Depending on the extent of the infection, the patient may have signs and symptoms of meningitis, encephalitis, or myelitis. A patient who has meningitis characteristically experiences intense headache, pain on flexion of the neck, and photophobia. Physical findings include fever and meningismus, with positive Kernig and Brudzinski signs (see Chapter 289, Meningitis). In patients with encephalitis, mental status changes such as lethargy, delirium, or hallucinations may be mistakenly attributed to intoxication or psychosis. Signs of myelitis include weakness or sensory loss in the extremities. A central nervous system (CNS) infection should be presumed in any child with fever who has an acute change in mental status or motor function.

## VIRUSES

### Enteroviruses

Enteroviruses are a common cause of aseptic meningitis and encephalitis in infants. Enteroviral infection may be heralded by the development of diarrhea, abdominal pain, or vomiting and occurs most often during the summer (see Chapter 248, Enterovirus and Evolving Infections). Nonpolio enteroviruses include coxsackieviruses A and B and echoviruses. Meningoencephalitis caused by enteroviral infections is typically a mild, self-limited disease. Echovirus infections commonly begin with a petechial rash. Coxsackievirus infections may be heralded by lesions of the palms, soles, and mouth (hand, foot, and mouth disease) (Figure 290-1). An enterovirus may infect a fetus transplacentally.

Cases of polio in the United States now occur primarily in children who are immigrants, in immunodeficient children, and among small communities of unimmunized children. Worldwide cases of polio decreased by more than 99% from 1988 to 2013. Outbreaks of polio persist in developing countries in Asia and Africa because of transmission of wild poliovirus, reinfection of polio-free areas, and outbreaks caused by vaccine-derived polioviruses.

## Chapter 290

# MENINGOENCEPHALITIS

Richard Young, MD, MPH

Infections of the meninges and underlying brain parenchyma can be differentiated into septic and aseptic categories. *Meningitis* caused by bacteria, fungi, and mycobacteria is classified as septic and characterized by fever, altered mental status, and purulent cerebrospinal fluid (CSF). Aseptic meningitis and encephalitis are most often the result of viral infection but less frequently result from infection by parasites, spirochetes, rickettsia, and prions. Encephalitis has also been implicated as a sequelae to immunization, neoplasm, or autoimmune process. Organisms located in the subarachnoid space may spread to the adjacent cortical mantle. When there are signs of both meningeal and cerebrocortical involvement, the term *meningoencephalitis* is appropriate.

**Figure 290-1** Coxsackievirus infections may be heralded by lesions of the palms, soles, and mouth (hand, foot, and mouth disease).

In 2014, a nonpolio enterovirus was associated with infectious encephalomyelitis in children living in Colorado. Symptoms included acute limb weakness and cranial nerve palsies. Magnetic resonance imaging (MRI) disclosed nonenhancing lesions in the gray matter of the spinal cord or brainstem. The CSF revealed a mild to moderate pleocytosis. Of the 6 specimens positive for rhinovirus or enterovirus, 4 were typed as enterovirus D68.

### Herpesvirus

Herpes simplex virus (HSV) encephalitis has a bimodal age distribution, with one-third of cases occurring in childhood. In a study conducted from 1994 through 2005, HSV accounted for 5% of 322 cases of acute encephalitis at the Hospital for Sick Children. In neonates, HSV may produce cutaneous disease, meningoencephalitis, or disseminated disease. Risk factors for neonatal infection include first episode of maternal infection during the third trimester, fetal scalp monitoring, preterm delivery, and maternal age younger than 21 years. Toll-like receptor 3 (TLR3) deficiency may predispose to HSV encephalitis in certain children, some of whom may experience a recurrence of encephalitis. Infection with HSV commonly produces a necrotizing encephalitis, and 50% of untreated cases are fatal. The CSF discloses elevation of both leukocytes (often granulocytes) and erythrocytes. The polymerase chain reaction (PCR) test may be initially negative and subsequently positive in later analyses. Two-thirds of patients who survive have neurologic sequelae, including epilepsy (44%) and cognitive deficits (25%). Mothers of infected infants often have no symptoms of herpes infection during or before gestation, which makes the diagnosis of a neonatal infection more difficult. For more information, see Chapter 266, Herpes Infections.

Most young children are seropositive for human herpesvirus type 6 (HHV-6). Type 6B is associated with the childhood illness, roseola infantum, which causes high fever and morbilliform rash. Infection with HHV-6 may occasionally cause meningoencephalitis in infants and may be acquired perinatally, leading to asymptomatic carriage (often nasal) or persistent neonatal infection. Infection with HHV-6 was the cause of one-third of first febrile seizures evaluated in an emergency department (ED). The CSF of 9 children disclosed no increase in white blood cells and normal glucose and protein; HHV-6 was detected by PCR in approximately 25% of samples.

Nervous system infection with Epstein-Barr virus (EBV) may involve the cortex, cerebellum, spinal cord, or peripheral nerves, resulting in a clinical picture of encephalitis, aseptic meningitis, transverse myelitis, or ascending polyneuropathy. Two-thirds of patients with EBV encephalitis had headache, and 48% developed seizures. The prognosis of EBV encephalitis is generally favorable, although in some patients, the infection may cause death or disability.

### Arboviruses

Arboviral infections caused by *Bunyavirus* species and togavirus are transmitted to humans by arthropods. Arbovirus meningoencephalitis typically occurs during

the summer and early fall. LaCrosse virus, the etiologic agent of California virus encephalitis, remains the most common cause of neuroinvasive disease in children. California virus encephalitis should be suspected in any child in a known endemic region who has signs of fever and cerebrocortical dysfunction. The course of California virus encephalitis is usually mild, with a fatality rate of less than 5%. Western equine encephalitis (WEE), an arboviral disease primarily of infancy, causes a more severe syndrome. Eastern equine encephalitis (EEE) has a predilection for infants and young children. EEE is the most severe of the arboviral diseases and frequently proves fatal. St Louis encephalitis (SLE) may occur in epidemic form in the Midwest and Southeast. Most infections produced by SLE are mild.

Other viral diseases may be transmitted by vectors. The virus that causes Colorado tick fever, a reovirus transmitted by rodent arthropods, produces a dengue-like illness in humans. Tick-borne encephalitis (TBE) is endemic primarily in Europe, the former Soviet Union, and Asia. West Nile virus (WNV) is principally transmitted by *Culex* mosquitoes. West Nile neuroinvasive disease (WNND) occurs most commonly in older adults, with children constituting only 4% of all WNND case subjects reported from 1999 to 2007 (443 cases). Children with WNND often develop signs of meningitis, whereas adults typically manifest signs of encephalitis. Even though cases of intrauterine transmission and possible transmission through breastfeeding have occurred, mothers should continue breastfeeding even in areas with WNV transmission.

Infections with lymphocytic choriomeningitis (LCM) virus, an arenavirus, may be acquired or congenital. Acquired infections may be transmitted directly to humans by infected laboratory rodents or domestic (pet) rodents. LCM may be asymptomatic in one-third of individuals or produce a clinical picture of aseptic meningitis, meningoencephalitis, or transverse myelitis. Congenital infection with LCM may resemble congenital toxoplasmosis or cytomegalovirus (CMV) infection with chorioretinopathy, hydrocephaly, or microcephaly.

### Rabies

Rabies, an encephalitis caused by the neurotropic virus, *Rhabdoviridae*, is transmitted by a bite, scratch, or droplet from an infected wild animal (eg, raccoon, bat) or an unimmunized domestic animal. Rabies has the highest case-fatality rate of any infection and causes an estimated 50,000 deaths worldwide, frequently in children who are bitten by rabid dogs. In the United States, however, rabies infections in children are often attributed to contact with rabid bats. Deaths from rabies has declined from more than 100 deaths per year a century ago to less than 5 per year. Because of the long incubation period of rabies, the exposure may occur overseas, as was the case of a 24-year-old US soldier who presented to an ED in New York with symptoms of right arm pain, vomiting, ataxia, anxiety, and difficulty swallowing. Eight months previously, while deployed to Afghanistan, the soldier was bitten by a feral dog on the right hand. His wound was cleansed, but he had not received rabies postexposure prophylaxis.

Most reported cases of rabies encephalitis have been fatal. Most reported cases of rabies encephalitis have been fatal. A 15-year-old girl who received antiviral therapy while in an induced coma recovered. A shorter latency to symptoms of rabies has been documented after transplantation, as was the case when multiple individuals contracted rabies less than 30 days after tissue was transplanted from a teenager who had unknowingly been bitten by a rabid bat. Clinical symptoms consisted of mental status changes and seizures. MRI disclosed cerebral edema, and pathologic examination of brain tissue disclosed viral inclusions consistent with Negri bodies.

### Viruses Associated With Childhood Exanthems

Although a rare occurrence, childhood viral infections such as rubella, adenovirus, influenza, CMV, rotavirus, and EBV (infectious mononucleosis) can cause meningoencephalitis.

In the prevaccination era, measles was a ubiquitous disease whose spread was facilitated by overcrowding. Records from Ellis Island document more than one-half of deaths at quarantine resulted from measles. Measles viruses cause meningoencephalitis in approximately 1 in 1,000 cases and within 4 to 7 days after onset of the rash. The severity of the neurologic illness (including irritability, drowsiness, and ataxia) does not seem to be related to the intensity of the systemic illness. Endemic transmission of measles ceased in the United States in 2000. Cases of measles nonetheless occur because of immigration (nearly 50% from the Philippines) and outbreaks among unvaccinated persons such as Amish communities in Ohio. There were 173 cases and 5 outbreaks of measles in the first five months of 2015. The CDC, Centers for Disease Control, attribute the multistate outbreak to a visitor to the Disneyland amusement park in California. The measles virus type B3 was identified as the same virus which caused a measles outbreak in the Philippines during 2014.

Mortality in patients with measles meningoencephalitis approximates 10%, and as many as one-half of survivors may have neurologic sequelae. An unusual syndrome of dementia and myoclonic seizures can develop in children 7 to 10 years after measles infection or immunization. This disorder results from a persistent measles infection known as *subacute sclerosing panencephalitis* (SSPE) (Figure 290-2). Data from the US measles epidemic during 1989 to 1991 suggest an incidence of 4 to 11 cases of SSPE per 100,000 cases of measles. Infants and younger children are at higher risk than children older than 5 years. A syndrome of subacute measles encephalitis has also been reported in immunosuppressed individuals. Although encephalitis and aseptic meningitis may occur following immunization with the measles, mumps, and rubella (MMR) vaccine, there is no increase in the incidence of these conditions, suggesting the vaccine was not causal.

Varicella-zoster virus (VZV) is a herpesvirus that causes chickenpox or herpes zoster (shingles) (Figure 290-3). Varicella may cause mild encephalitis or a focal cerebellitis with prominent ataxia. Reactivation of VZV may produce a number of neurologic syndromes,

**Figure 290-2** Subacute sclerosing panencephalitis (SSPE). Marked atrophy of both the cerebral cortex and the deep gray nuclei has occurred in this child, who has long-standing SSPE.

**Figure 290-3** Varicella-zoster virus (VZV) is a herpesvirus that causes chickenpox or herpes zoster (shingles). This child received a VZV vaccination 2 months before eruption of herpes zoster.

including encephalitis, myelitis, stroke, and acute infectious demyelinating polyneuropathy (AIDP, Guillain-Barré syndrome).

Rubella is a mild febrile exanthem of childhood with prominent arthralgia. Infection during the first trimester of pregnancy may result in congenital rubella syndrome. The number of cases has declined from 57,686 in 1969 to 271 in 1999. Rubella in the United States now primarily affects infants born to foreign-born

women. A child affected with rubella in utero may be infectious for 12 months or more.

Mumps meningoencephalitis is a mild illness that generally has a good prognosis. One-half of children with mumps meningoencephalitis are asymptomatic, whereas 15% may exhibit meningismus and headache. Mumps meningoencephalitis may occur without parotitis, before the appearance of parotitis, or after it has resolved.

### Immunizations for Viral Diseases

#### Influenza

Neurologic complications such as seizure or altered mental status have been reported with the novel influenza A (H1N1) virus. The most common complication was simple or complex febrile seizure in 12 of 17 patients. Less frequent neurologic disorders associated with H1N1 infection included encephalopathy, Guillain-Barré syndrome, acute disseminated encephalomyelitis, and transverse myelitis.

#### Rotavirus

Immunization with rotavirus is now recommended by the American Academy of Pediatrics and the Advisory Committee on Immunization Practices. More than 20 cases of meningoencephalitis have been reported with confirmation of rotavirus in the CSF by PCR.

#### Postvaccinal Encephalitis

Postvaccine encephalitis is a rare but serious complication of measles or other live vaccines. Following smallpox vaccine (vaccinia), the attenuated virus may cause encephalitis, with permanent neurologic injury in 25% of those affected. Children younger than 1 year are at greatest risk. Vaccinia virus may be detected in brain or CSF of children with vaccinia meningoencephalitis. Since 1971, routine vaccination was discontinued. Currently, certain laboratory workers and US service members who are being deployed have been inoculated with vaccinia virus. Transmission of vaccinia could occur if a susceptible individual, such as a child with eczema, is in close contact with a recently vaccinated family member.

### Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS) is caused by the HIV retrovirus (see Chapter 268, Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome). The syndrome is noteworthy for meningoencephalitis caused by HIV and by CMV, herpesvirus, and *Toxoplasma gondii*. Nervous system involvement in patients infected with the HIV virus also includes development of lymphoma, progressive multifocal leukoencephalopathy associated with JC virus, and infections with *Cryptococcus*, tuberculosis, and *Candida albicans*. Infection with HIV may produce either encephalitis or a progressive encephalopathy in children. Multiple organisms, including viruses, bacteria, fungi, and protozoa, can be recovered from brain tissue of immunosuppressed patients who have AIDS.

### Fungi, Spirochetes, and Parasites

Nonviral causes of meningoencephalitis include infectious (fungi, spirochetes, and parasites) and noninfectious conditions associated with CSF pleocytosis.

Amebic meningoencephalitis may result from swimming in infected freshwater rivers or lakes infected with *Naegleria*. (See Chapter 308, Parasitic Infections.)

In 2012, the incidence of mother-to-child transmission of syphilis (MTCTS, or congenital syphilis) declined to 7.8 cases per 100,000 live births. The rate of MTCTS in infants born to black women was more than 4-fold greater (29.6 cases per 100,000 live births), indicating inadequate prenatal care. MTCTS may result in premature birth or stillbirth. Infected newborns may be asymptomatic or may present with hepatosplenomegaly, petechial rash ("blueberry muffin baby"), rhinorrhea (snuffles), or bony abnormalities.

Neuroborreliosis is a tick-borne spirochetal infection. In addition to headache, neurologic disorders occurring in individuals with neuroborreliosis include facial palsy (8%), radiculopathy (1%), and meningitis-encephalitis (1%). Some children with facial nerve palsy caused by *Borrelia burgdorferi* had CSF pleocytosis (predominantly mononuclear; average number of cells, 191/mcL) or increased CSF protein but lacked meningeal signs. Children with Lyme disease are also at risk for developing transverse myelitis, seizures, pseudotumor, diplopia, headache, and meningismus.

Tick-borne encephalitis include Rocky Mountain spotted fever (RMSF) caused by *Rickettsia rickettsii*. Similar illnesses may be produced by infection with other rickettsial species (eg, spotted fever group *Rickettsia*). RMSF is transmitted by several species of ticks. The initial symptoms are protean, including fever and malaise. The classic petechial rash develops by the fifth day. Children aged 5 to 9 years are at the highest risk for fatal outcome. Pet dogs may concurrently develop RMSF and serve as a vector. Native American children suffer significantly more infections from RMSF than other ethnic groups.

Toxoplasmosis causes cerebral calcifications, microcephaly, and seizures resulting from transplacental infection by the protozoa *T gondii* to the fetus. An estimated 400 to 4,000 cases of congenital toxoplasmosis occur each year, transmitted to humans through ingestion of inadequately cooked meat or ingestion of oocysts from cat feces.

### Prions

The transmissible spongiform encephalopathies include kuru (children of the Fore tribe of New Guinea), bovine spongiform encephalopathy (BSE) (cattle), and Creutzfeldt-Jakob (CJ) disease (humans). Of the 15 cases of CJ disease in individuals younger than 30 years during the time period 1979 to 2006, one-half of the cases contracted the disease through administration of cadaveric growth hormone or dura mater transplants. New-variant CJ disease is a foodborne disorder related to BSE, which is endemic in the United Kingdom. Susceptibility to new-variant CJ disease may be highest in teenagers. Prohibition of beef products in cattle feed has reduced the incidence of both new-variant CJ disease and BSE.

### INCIDENCE

The number of annual viral encephalitis cases in the United States is estimated at 20,000 each year. The pathogens most commonly responsible for viral

encephalitis include enteroviruses, HSV (responsible for 10% of cases), arboviruses (eg, WNV), and rabies virus. Deaths associated with encephalitis were highest in children younger than 1 year and adults older than 65 years in the 20-year period from 1979 to 1998. Viruses reported as producing encephalitis in individuals younger than 25 years in 2012 included WNV, 175; California virus, 60; and EEEE, 4. There were no cases of rabies in those younger than 25 years. Congenital rubella was noted in 3 infants; the mothers of all 3 had been in Africa during their pregnancy. Treponemal infection (congenital syphilis) was reported in 322 infants.

## CLINICAL FEATURES

Most viruses spread through the bloodstream to the choroid plexus and from there to the parenchyma of the cerebrum, brainstem, or spinal cord. Clinical features of cerebral involvement are most commonly seizures and changes in mental status. Rabies travels in a retrograde manner through the peripheral nerves to invade the brainstem, producing cranial neuropathies, such as drooling and choking on liquids (“hydrophobia”). Herpes simplex virus classically infects the temporal lobes, resulting in olfactory seizures (“bad smells”). As the virus spreads from the temporal region, focal or generalized convulsive activity develops.

Poliomyelitis selectively affects the motor neurons, resulting in paralysis of the muscles of respiration (bulbar paralysis) and extremities. Paralysis of the legs can be asymmetrical. Enterovirus D68 is associated with limb weakness and involvement of the spinal gray matter. Varicella-zoster and EBV may infect the cerebellum, producing an acute ataxia. If spinal cord involvement is present, then the patient may have symmetrical limb paralysis, transverse sensory symptoms, and bowel and bladder dysfunction.

Children with aseptic meningitis, in contrast to those with meningoencephalitis, have intense headache, meningismus, and photophobia but may possess a clear sensorium. Ameba, fungi, and the viruses causing EEE, HSV, or rabies may produce cerebral or brainstem dysfunction, intractable seizures, increased intracranial pressure from brain edema, and death.

Ultimately, the course and outcome of meningoencephalitis are related to the virulence of the organism and the host response to the infection. For every 100 individuals excreting poliovirus in their feces, 1 is paralyzed; approximately 5 others have nonspecific sore throat, nausea, vomiting, or flu-like symptoms (abortive poliomyelitis); and 94 are asymptomatic.

## DIFFERENTIAL DIAGNOSIS

The early signs and symptoms associated with viral infection of the nervous system are often protean and include fever, chills, myalgia, and headache. It is frequently challenging for the pediatrician to distinguish “just a cold” from the early stages of meningoencephalitis. Change in mental status is the sine qua non of meningoencephalitis. Nonetheless, change in mental status because of toxins or metabolic derangement must be excluded when considering a diagnosis of meningoencephalitis. Metabolic encephalopathy resulting from hypoglycemia, hyperammonemia, and

Reye syndrome can be diagnosed by appropriate laboratory investigations. When meningoencephalitis is suspected, make certain to exclude the possibility of toxic exposure to lead, alcohol, acetaminophen, or other poisons that could produce encephalopathy.

The clinical course of a brain abscess is usually slower than occurs in meningoencephalitis. Focal findings may be prominent in brain abscess, and a history of sinus infection, middle ear or mastoid infection, or congenital heart disease may be elicited. A myelitic form of viral nervous system infection may be mimicked by a mass lesion or Guillain-Barré syndrome. Differences in seasonal occurrence, clinical course, and outcome allow differentiation of some types of meningoencephalitis.

Demyelinating disease in children may present as a postinfectious inflammation of the brain and spinal cord termed *acute disseminated encephalomyelitis* (ADEM). Varicella and rubella have been implicated as causes of ADEM, but in many cases, no definite virus is identified. CNS demyelinating disease evolves over several days, producing altered mental status, visual loss, paralysis, or seizure. Magnetic resonance imaging may disclose marked signal abnormalities in the subcortical white matter, corpus callosum, cerebellum, brainstem, or spinal cord. Autoantibodies against myelin oligodendrocyte glycoprotein (MOG) may be present in 44% of patients with ADEM but only 2% of patients with multiple sclerosis. Serum aquaporin-4 (AQP4) antibodies can differentiate neuromyelitis optica (NMO), a demyelinating disorder with prominent involvement of the optic nerve and spinal cord.

N-methyl-D-aspartate (NMDA) receptor antibody encephalitis (also termed *anti-NMDA receptor antibody encephalitis*) may produce a syndrome similar to infectious encephalitis with altered sensorium, intractable seizures, movement disorder, MRI abnormalities in the white matter or brainstem, and autonomic dysfunction. One-third of teenage girls with NMDA receptor encephalitis may have ovarian teratomas.

## LABORATORY EVALUATION

Examination of the CSF may be helpful to the diagnosis of meningoencephalitis. However, there may be considerable overlap in the CSF formula that results from viral, bacterial, or fungal infection of the nervous system. In some cases of meningoencephalitis, pleocytosis may be minimal or absent. For example, only 50% of patients positive by PCR for enterovirus infection in CNS had pleocytosis in the CSF. Similarly, the degree of hypoglycorrhachia and protein elevation in CSF varies with type of organism. Every attempt should be made to identify the offending organism to help determine the prognosis and to document potential epidemic outbreaks.

The presence of red blood cells in the CSF may indicate hemorrhagic brain necrosis, commonly seen with herpesvirus infections and EEE. A predominance of mononuclear cells in the CSF is the exception in acute bacterial meningoencephalitis but may be present with syphilis, Lyme disease, listeriosis, or tuberculosis.

Polymerase chain reaction is a powerful tool in identifying enterovirus, mumps virus, CMV, VZV, and other viruses. In adult patients with herpes simplex

encephalitis, PCR of CSF has more than 90% specificity and sensitivity. The reliability of PCR in neonatal HSV may vary according to the assay used in a specific laboratory. A rapid screening test for EBV (Monospot) is available at most hospitals. Brain biopsy is seldom used as a diagnostic tool. Viral culture of CSF has the advantage of detection of viruses not included in the PCR panel, but the disadvantage of being falsely negative. A positive PCR may raise the question of whether presence of viral antigen represents new or prior infection. Comparison of serum and CSF titer may be helpful in this situation.

Brain imaging in children suspected of viral encephalitis is essential. A caveat is that the computed tomographic brain scan, although rapid and widely available, lacks the sensitivity of MRI in discerning edema formation and inflammation. Even MRI may be normal in the early phases of meningoencephalitis. Contrast should be administered to better assess inflammation or cerebral cortical enhancement. Typical MRI findings in meningoencephalitis include scattered or confluent areas of T2-weighted hyperintensities or T1-weighted hypointensities. When the encephalitis produces cerebral edema, MRI may disclose midline shift, ventricular compression, or cerebral cortical effacement. Temporal lobe enhancement or necrosis may be evidence of herpesvirus infection.

An electroencephalogram can be a useful adjunctive test. Infants with HSV often have periodic (2-Hz) lateralized epileptiform discharges in the temporal region.

In summary, MRI with and without contrast is promptly performed in the child with suspected viral meningoencephalitis. The spinal cord should also be imaged if signs of myelitis or radiculitis are present. Samples of CSF and blood are obtained for PCR, cell count and differential, glucose, and protein. Serologic tests should be obtained during the acute and convalescent phases of the disorder. Viral culture of CSF, throat, and stool should also be considered if the PCR is not diagnostic.

## TREATMENT

In a child suspected of having meningoencephalitis, after imaging and laboratory studies have been obtained, treatment with intravenous acyclovir is considered. Acyclovir is indicated for HSV infection, with higher doses (60 mg/kg per day) recommended for neonates. Renal function should be monitored because acyclovir is nephrotoxic. Ganciclovir has been used in treatment of VZV-associated encephalitis, HHV-6, and CMV infection.

Specific treatment of other viral encephalitides remains elusive. In 2004, a 14-year-old girl with rabies responded to the combination of ribavirin, ketamine, and amantadine. However, subsequent treatment of 3 other children with rabies infection was unsuccessful. The management of encephalitis caused by HIV is discussed in Chapter 268, Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome. Corticosteroids are not of proven benefit in treating viral meningoencephalitis and may blunt host defenses.

Encephalitis caused by agents other than viruses are treated appropriately. Rickettsial infection of the

nervous system is treated with doxycycline. *Borrelia* infection should be treated with ceftriaxone, and treponemal infection with penicillin.

Supportive treatment of a patient who has meningoencephalitis includes management of intracranial pressure (see Chapter 364, Increased Intracranial Pressure), respiratory support, treatment of seizures, physical therapy, and maintenance of fluid and electrolyte balance.

Prevention is the most cost-effective method of reducing the morbidity and mortality caused by viral meningoencephalitis. Immunization has reduced, but not eliminated, poliomyelitis, and has made rubella, mumps, and measles meningoencephalitis uncommon. Repeat measles immunizations of older children should reduce the incidence of measles encephalitis and SSPE further.

## PROGNOSIS

The prognosis of meningoencephalitis is related to the virulence of the organism and the age, neurologic status at time of treatment, and immune status of the host. At one extreme, rabies encephalitis is almost always fatal. In contrast, all children with respiratory syncytial virus encephalitis have a full recovery.

The development of antiviral therapy has profoundly affected prognosis in HSV encephalitis. Without antiviral therapy, more than two-thirds of individuals with HSV encephalitis will die, and fewer than 5% regain normal neurologic function. With acyclovir therapy, no deaths were reported from childhood HSV encephalitis, but neurologic sequelae developed in 63% of patients. Infants with HSV-1 encephalitis have better neurologic outcomes than those infected with HSV-2. Developmental scores were significantly higher in infants with neonatal HSV who received oral suppressive therapy with acyclovir for 6 months after their initial intravenous course of antiviral therapy.

In contrast to HSV encephalitis, the prognosis of EBV encephalitis was considerably better: death in 10%, mild neurologic sequelae in 10%, and good neurologic outcome in 80%.

The outcome of arbovirus infections is on a spectrum. Eastern equine encephalitis caused death in one-third of patients, with many of the survivors suffering severe neurologic consequences. In some of the arboviral infections, children are affected more severely than adults. WEE is associated with complete recovery in virtually all adults but causes death in 3% and neurologic sequelae in up to 30% of children. Venezuelan equine encephalitis causes flu-like symptoms in adults, with encephalitis occurring most frequently in children. Similarly, deaths from Japanese encephalitis may be 3-fold greater in children than adults.

A bimodal involvement is seen with RMSF. Children aged 5 to 9 years have the highest risk for death, as do adults older than 70 years.

The neurologic consequences of meningoencephalitis may be lasting. Enterovirus 71 infection of the CNS in children was associated with a nearly 7-fold increase in attention deficit/hyperactivity disorder-related symptoms (20% of children with meningoencephalitis vs 3% of matched control subjects).

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 291

# METABOLIC DISORDERS BEYOND THE NEWBORN PERIOD

Carol Lynn Greene, MD

## FOUNDATION

### Definition, Epidemiology, Etiology, and Risk Factors

At a conservative estimate, inborn errors of metabolism (IEMs) collectively affect more than 1 per 1,000 individuals. These errors can present at any age and affect any organ system. Many IEMs respond to specific therapies that prevent disability or death, and all are genetic. The failure to suspect and diagnose inborn errors leads to lost opportunities for intervention, resulting in harm to children and families. Appropriately integrating approaches to diagnosing IEMs in pediatric practice yields some of the highest benefits in medicine (Box 291-1). This chapter covers the basic principles and approaches to IEMs, with an emphasis on signs and symptoms for a practical clinical understanding for the primary care physician (PCP) and for nongenetic specialists. In addition, the PCP of the medical home should ensure that families are aware of options for carrier screening because families may be interested in understanding and possibly addressing risks in advance.

Understanding basic principles, presentations, and approaches to IEMs increases the likelihood of prompt

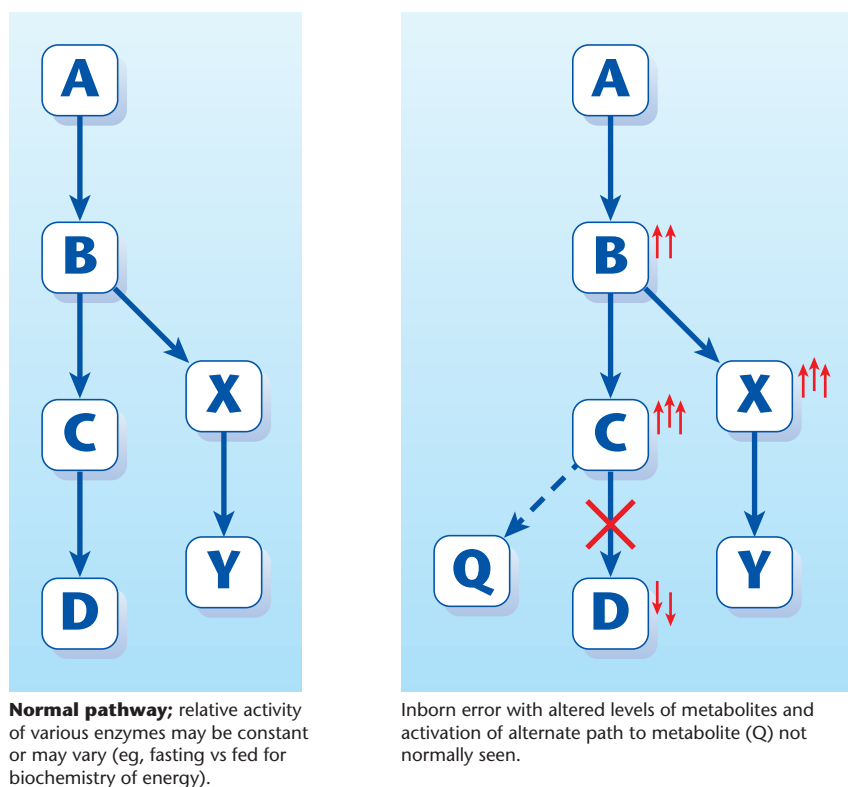

### BOX 291-1 Case 1

A 3-month-old infant is brought to the primary care physician (PCP) with reports of irritability and frequent vomiting. A diagnosis of reflux is made, and treatment measures are somewhat helpful. Weight gain slows over the next few months. At the 9-month visit, the PCP notes inadequate developmental progress. Further evaluation over the next 8 months involves multiple invasive studies, and eventually a combination of urine and blood studies reveals a diagnosis of an inborn error of metabolism. The diagnostic odyssey is over. The condition is autosomal recessive, so the 2-month-old sibling is tested and is also affected.

The diagnosis is methylmalonic acidemia, of a type profoundly responsive to B<sub>12</sub> therapy. The patient responds to treatment that prevents further brain damage. Unfortunately, the patient has permanent brain damage that could have been prevented if the diagnosis had been made at 4 months of age. The affected sibling will benefit from earlier treatment.

If the diagnosis were mitochondrial depletion syndrome (a fatal condition caused by an identifiable mutation in polymerase gamma), prenatal diagnosis would have been available to the family, who must anticipate the early demise of both of their children.

**Figure 291-1** Normal and abnormal metabolic pathway and consequences.

recognition, diagnosis, and appropriate management for patients and their families.

### Defining Inborn Errors of Metabolism: Basic Principles, Types, and Pathophysiology

IEMs are conditions in which a change in gene alters the function of an enzyme or other protein. The change in function causes alterations in a metabolic pathway that leads to clinical consequences. A block in a pathway can lead to the increase of a compound normally present but toxic in excess (eg, ammonia or methylmalonic acid); to inadequate levels of some essential metabolic product (eg, glucose, or adenosine triphosphate for energy); or to production through an alternative pathway of a toxic compound that is not normally present (Figure 291-1).

Some categories of IEMs are identified by the types of molecules involved and some by the organelle into which a certain aspect of metabolism is compartmentalized. Some involve small molecules, and some involve very large molecules. In many categories of IEMs there is more than one kind of pathophysiology. The primary metabolic defects range from simple catalytic failure of an enzyme, failure of post-translational modification of multiple enzymes and other proteins, failure to transport enzyme to appropriate metabolic compartment, failure of production or activation of a cofactor essential for enzyme activity, or complete failure to build a cellular compartment.

Any system of categorization is imperfect. For example, pyruvate carboxylase deficiency is here

categorized as an inborn error of mitochondrial energy metabolism. However, pyruvate carboxylase deficiency may also be part of multiple carboxylase deficiency or biotinidase deficiency. In that case pyruvate carboxylase deficiency is found together with abnormalities of other enzymes that are clearly inborn errors of organic acid metabolism. Other important examples are the disorders of cobalamin ( $B_{12}$ ) metabolism that can cause either altered metabolism of methylmalonic acid (organic acidemia) or homocystine (amino acidopathy), or both, depending on the step in the cobalamin pathway that is altered. Maple syrup urine disease (MSUD) can be classified as an amino acid disorder or organic acidemia depending on the aspect of the biochemistry that is considered. No attempt is made to categorize certain biochemical conditions such as glucose transporter defect (a cause of seizures) and  $\alpha_1$ -antitrypsin deficiency (cause of liver disease in children) that do not fit into any biochemical model of categorization. They are included as appropriate in the recommendations for evaluation of clinical presentation. However, certain biochemical conditions that are traditionally covered elsewhere are not included here, such as the inborn errors of steroid metabolism (eg, congenital adrenal hyperplasia) and the albinisms, although some of the latter conditions are lysosomal disorders and others are abnormalities of metabolism of tyrosine. Table 291-1 provides a practical classification for consideration of pathophysiology and presentation and for use in directing first steps in consideration of the differential diagnosis and evaluation. Inheritance is typically

Table 291-1

## Categories of Inborn Errors of Metabolism With Key Characteristics and Examples

## CATEGORY, DEFINITION, BIOCHEMISTRY, AND GENETICS

## KEY CHARACTERISTICS AND EXAMPLES

**Aminoacidopathies:** Involve abnormal levels of AAs with the amino group still attached; include primary catalytic defects, cofactor defects, transport defects (note that MSUD may be categorized here because AA levels are elevated in blood). Almost all are autosomal recessive.

Usually not acidotic (except MSUD, or with the renal tubular acidosis of tyrosinemia). Typically but not always affect the CNS (eg, PKU, glycine encephalopathy), may affect other organs (eg, liver and renal tubules in tyrosinemia type 1). Episodic, static, or progressive. Homocystinuria may present with stroke or clotting, with or without intellectual disability. Diagnosis with blood AA (PAA or SAA), sometimes UAA, sometimes confirmed by enzyme assay or DNA testing.

*Special presentation:* when the mother has PKU or hyperphenylalaninemia, she may be normal and unaware of diagnosis but have babies with microcephaly and intellectual disability; this has nearly 100% recurrence risk, and adverse outcome is preventable with treatment of mother; diagnosed by blood AA in mother.

**Organic acidemias:** Involve metabolites of AAs after amino group is removed and other compounds with C, H, and O (fatty acids and lactate/energy in separate categories). Essentially all are autosomal recessive.

Usually but not always acidotic, anorexia/vomiting; episodic altered consciousness; may include bone marrow depression or other end-organ failure. Diagnosis with UOAs; blood ACP may be helpful, enzyme assays or DNA testing for confirmation when available.

**Urea cycle defects:** Involve the urea cycle, typically with altered levels of the AAs in the urea cycle. Most are autosomal recessive, but the most common is X-linked.

Altered mental status, decreased appetite or intractable or recurrent emesis including “cyclic vomiting,” migraine, ataxia, and often with protein aversion. Typically not acidotic unless in shock; respiratory alkalosis is common. Diagnosis by blood AA, in some cases confirmed with enzyme assays or DNA testing.

**Fatty acid oxidation and carnitine metabolism disorders:** Involve the oxidation of fatty acids to ketones and the transport of fatty acids into the mitochondria for oxidation. Essentially all are autosomal recessive.

Classic presentation is Reye syndrome or SIDS in an infant or toddler, but more commonly the presentation is excessive irritability or lethargy with ordinary childhood illness or extended fasting. The hallmark is hypoketosis, but some ketones are usually present, and hypoglycemia is only sometimes present. Also may present (especially long-chain fatty acid oxidation and carnitine metabolism) with liver failure, FTT, cardiomyopathy, or rhabdomyolysis; retinopathy and bone marrow failure may occur. Diagnose with ACP, but that may be normal when well, and diagnose some conditions with carnitine levels. Some diagnoses may be confirmed with enzyme assays and/or DNA testing.

**Mitochondrial (energy) metabolism and disorders of lactate and pyruvate:** Include oxidative phosphorylation defects of the mitochondrial respiratory chain, defects of the Krebs cycle and of PDH and pyruvate carboxylase. May occur because of defects of single enzymes, of transport into the mitochondria (of enzymes or substrate), of cofactor synthesis (eg, coenzyme Q), of multiple enzymes because of mutations in mitochondrial DNA (mtDNA) or of mtDNA repair or synthesis. X-linked inheritance (PDH deficiency and some creatine disorders), autosomal dominant inheritance, and maternal inheritance because of mtDNA mutations occur; but most conditions are autosomal recessive.

Any presentation, any age, with variability in biochemical findings and clinical presentation. Examples include dysmorphic features with brain dysgenesis or porencephalic cysts; the normally formed neonate with overwhelming acidosis; Leigh syndrome (an infantile or childhood-onset brainstem neurodegenerative disease); isolated organ failure of heart, liver, kidney, exocrine pancreas, bone marrow, retina, or others; and combinations, eg, Pearson syndrome (bone marrow and exocrine pancreatic failure) or multisystem failure. Other classic pediatric conditions are MELAS, MERRF, and Alpers syndrome (progressive seizures and liver failure). Diagnostic testing depends on presentation; usually begins with blood AA and UOA, lactate and pyruvate, and ACP; but in some cases the first diagnostic test is of DNA sample of blood or biopsy of muscle or liver for histochemistry or enzyme assays. It is well described that enzyme assays or DNA findings can be normal in cases with proven disease.

**Carbohydrate disorders:** Involve metabolism of sugars (with glycogen storage disorders separated out); examples are galactosemia and the disorders of fructose metabolism. Essentially all are autosomal recessive.

Typically presenting with liver disease or hypoglycemia and acidosis, often with renal tubular disease. Cataracts may be seen in galactosemia at presentation in some cases and develop in untreated cases. Diagnosis based on enzyme assay or DNA testing.

Continued

Table 291-1

## Categories of Inborn Errors of Metabolism With Key Characteristics and Examples—cont'd

CATEGORY, DEFINITION, BIOCHEMISTRY, AND GENETICS	KEY CHARACTERISTICS AND EXAMPLES
<b>Glycogen storage disorders:</b> The various disorders of glycogen synthesis and degradation; when glycogen is not normally branched, there are adverse effects on the liver. Most are autosomal recessive, and some are X-linked.	Typically but not always including hepatomegaly, 2 major presentations are seen, with hypoglycemia (eg, glycogen storage disease [GSD] type 1) or with muscle weakness with or without cardiomyopathy and rhabdomyolysis (Pompe disease, McArdle disease). Some conditions lead to liver failure or liver tumors. However, glycogen synthase deficiency is GSD type 0 and presents as ketotic hypoglycemia with a small liver. Diagnosis by histology, enzyme assay, DNA testing for some conditions.
<b>Porphyrias:</b> Disorders of metabolism of the porphyrins in synthesis or degradation of hemo-globins. AIP is autosomal dominant; others are recessive or X-linked.	Most cases present in late childhood or adolescence, with or without skin findings, but some types present in the neonate. CNS is typically spared, but AIP and hepatic coproporphyrin can present with psychotic episodes, recurrent abdominal pain, and peripheral neuropathy, often diagnosed as psychosomatic disease. Diagnosis includes biochemistry, enzyme assay, and DNA testing for some conditions.
<b>Lysosomal storage diseases:</b> Disorders resulting from alteration of function of individual enzymes responsible for breaking down large cell wall molecules (mucopolysaccharides, glycolipids, sphingolipids) within the lysosome, or of import into the lysosome affecting multiple pathways. Most are autosomal recessive, and Hunter syndrome and Fabry disease are X-linked.	Progressive disorders that until recently were untreatable. Some affect the CNS only (Krabbe disease), whereas others also have organomegaly (Tay-Sachs disease), dysmorphic features, and skeletal changes (the mucopolysaccharidoses, except for Sanfilippo syndrome that affects primarily CNS). Cystinosis affects bone by causing renal tubular disease. Hepatosplenomegaly of Gaucher disease leads to preventable anemia and thrombocytopenia. Fabry disease is especially underdiagnosed and untreated; it causes renal failure (typically in early or middle adulthood), cardiomyopathy, stroke, and pain from peripheral neuropathy; enzyme infusion prevents permanent damage. Diagnose by biochemistry (eg, UMPs or oligosaccharides in some), enzyme assay, DNA testing for some conditions, or carrier testing which is available for some conditions.
<b>Peroxisomal disorders:</b> Disorders of individual enzymes in the peroxisome involved in various pathways including very-long-chain fatty acid oxidation and plasmalogen synthesis, or defects of peroxisome development leading to multiple pathway dysfunction.	A wide variety of presentations including the neurodegenerative condition adrenoleukodystrophy or isolated primary adrenal failure. May present as a dysmorphic syndrome; as Zellweger syndrome; with Down syndrome-like facies, hypotonia, and liver and renal cysts; and as progressive neurodegenerative disease. Most have alteration of either very-long-chain fatty acids, plasmalogens, or pipecolic acid, and some have stippled epiphyses on plain film. Diagnose with histology and biochemistry and with DNA testing in some conditions.
<b>Disorders of purines and pyrimidines:</b> Disorders of synthesis or degradation; include disorders of uric acid metabolism. Autosomal recessive or X-linked.	Variable presentation, mostly affecting the CNS or the bone marrow (eg, severe combined immunodeficiency). Include Lesch-Nyhan disease, with self-mutilation; the same enzyme defect in milder cases causes gout. Diagnose with biochemistry; DNA testing in some conditions.
<b>Neurotransmitter disorders (and other conditions evident only on analysis of cerebrospinal fluid):</b> These are conditions in which critical neuroactive molecules are not properly synthesized or metabolized. Include a number of conditions in which cofactor metabolism is the primary problem, including B <sub>6</sub> responsive seizures and disorders of pterin metabolism. Most are autosomal recessive.	By definition, these are conditions that affect function of the central or peripheral nervous system. Typical presentations include seizures, irritability or other altered mental status, and abnormalities of tone and development. Indirect evidence may be present, (eg, low prolactin in blood resulting from low dopamine), or response to pyridoxine trial, but in general collection and handling of spinal fluid need special precautions for diagnosis. Diagnosis with biochemistry of spinal fluid; some can be confirmed with enzyme assay or DNA testing.
<b>Disorders of metals and micronutrients:</b> Conditions that involve altered metabolism of metals, and some micronutrients including iron, copper, and molybdenum; they can involve excess storage or inability to incorporate metal into enzymes for which it is a critical component. Recessive or X-linked and in some forms of hemochromatosis complex with asymptomatic homozygotes and symptomatic heterozygotes.	Disorders of copper include Menkes disease (neonatal seizures with unusual hair) and Wilson disease (progressive CNS or liver disease). Disorders of iron in pediatrics include neonatal hemochromatosis, presenting with liver disease, or rare late childhood presentation of classic hemochromatosis, causing initial nonspecific symptoms resulting in arthritis or single or multiple organ failure (typically liver, heart, or diabetes). This list does not attempt to consider the primary disorders of molybdenum, zinc, and other micronutrients. Diagnose with metal levels, other biochemistry, histology, and histochemistry; DNA testing in some conditions.

Table 291-1

## Categories of Inborn Errors of Metabolism With Key Characteristics and Examples—cont'd

## CATEGORY, DEFINITION, BIOCHEMISTRY, AND GENETICS

## KEY CHARACTERISTICS AND EXAMPLES

**Disorders of connective tissue (collagen, fibrillin, elastin):** Not to be mistaken for the term *connective tissue disorder* meaning autoimmune disorders, these are typically disorders of structural proteins that affect the integrity of the connective tissue of selected or all organs. Recessive, dominant, or X-linked.

Usually considered in general genetics. Abnormal collagen may primarily affect bones causing osteogenesis imperfecta (with or without dental and hearing problems) or may affect joints and skin, with some causing rupture of vessels or hollow organs. Fibrillin mutations cause Marfan syndrome, and elastin mutations cause Williams syndrome. Diagnosis is by clinical evaluation; in some cases confirmed by DNA testing or by biochemistry of the altered molecule in tissue.

**Carbohydrate-deficient glycoprotein disorders:** Disorders that involve multiple biochemical pathways because the primary disorder is a failure of  $\geq 1$  enzymes that attach carbohydrate moieties to proteins (including enzymes) required for correct structure and function of the protein. Most are autosomal recessive.

As a group, there are now more than 30 conditions identified with highly varied presentation, including conditions with dysmorphic features and malformations evident in the neonate, and others that present only much later; the classic “type 1A” has cerebellar hypoplasia. Often with involvement of the CNS and peripheral nervous system, and includes some primary muscular dystrophies. Some have acute episodes of metabolic crisis or organ failure and many have FTT. Diagnosis is by examination of blood for altered pattern of carbohydrates attached to various proteins, many can be confirmed by DNA testing and some by enzyme assay.

**Channelopathies:** Altered transport of ions across cell walls, including especially calcium. The classic disorder of transport, cystic fibrosis, is not typically considered an inborn error of metabolism but does fit the category. Recessive, dominant, or X-linked.

Leaving aside cystic fibrosis, the 2 major presentations of conditions in this category are neurologic (progressive ataxias, seizures, including heritable febrile seizures or progressive seizure disorders) or cardiac arrhythmias (including classic long QT syndrome). Typically without acidosis or altered organ function except for the primary presentation. Diagnosis is clinical, confirmed in some cases by DNA testing.

**Disorders of cholesterol and other sterol metabolism (primarily synthesis):** Alteration in the synthesis of cholesterol and other sterols; pathophysiology may be because of inadequate amounts of an essential metabolite or interference from the abnormal metabolites. Typically autosomal recessive.

Presenting with FTT, neurologic disease, and often with birth defects and skin disease, this category includes a previously well-described autosomal recessive dysmorphic syndrome (Smith-Lemli-Opitz syndrome). These disorders typically include feeding disturbance and hypotonia and may have skin pigment abnormalities. Diagnosis by biochemistry; cholesterol may be low, but measurement of cholesterol alone is not adequate to make or exclude a diagnosis of any of these conditions. Diagnosis depends on demonstration of abnormal patterns of sterols; some may be confirmed with DNA testing.

**Disorders of vitamins and cofactors:** Vitamins and other cofactors must be absorbed and transported across membranes, and many must be metabolized to an active form or synthesized in the human cell. Pathophysiology of these conditions depends on the pathway. Typically autosomal recessive, but X-linked and dominant disease is known.

This category crosses almost all boundaries because cofactors are found in many pathways. Presentation can be systemic or more limited to the nervous system, bone marrow, bones, muscle (including cardiac), or skin. As an example, problems with vitamin B<sub>12</sub> (cobalamin) can alter AA metabolism, organic acid metabolism, or both. An abnormality of vitamin D leads to X-linked rickets, and an abnormality of pterin metabolism leads to autosomal dominant dopa-responsive dystonia, also known to neurologists as Segawa syndrome. Failure to synthesize coenzyme Q10 leads to a particularly reversible disorder of energy metabolism. Diagnosis of a disorder of vitamin or cofactor metabolism is based on measurement of appropriate metabolites and on measurement of levels of specific vitamins or cofactors. In some cases there is functional testing (eg, enzyme assay for biotinidase, and enzyme assay and complementation studies for cobalamin disorders). Often can be confirmed by DNA testing.

AA, amino acids; AIP, acute intermittent porphyria; ACP, acylcarnitine profile; CNS, central nervous system; FTT, failure to thrive; MELAS, mitochondrial encephalopathy, lactic acidosis, and stroke; MERRF, myoclonic epilepsy, ragged red fibers; MSUD, maple syrup urine disease; OA, organic acid; PAA, plasma amino acid; PDH, pyruvate dehydrogenase; PKU, phenylketonuria; SAA, serum amino acid; SIDS, sudden infant death syndrome; UAA, urine amino acids; UMPS, urine mucopolysaccharide; UOA, urine organic acids.

autosomal recessive, with some X-linked conditions and with a few autosomal dominant conditions and maternal inheritance for some cases of mitochondrial disease.

### Risk Factors

Any person of any age and in any population could have an IEM. However, certain IEMs are seen with increased frequency in some populations. For example, Tay-Sachs disease is seen with increased frequency in those of Ashkenazi Jewish or Acadian ancestry. Consanguinity is a risk factor for an IEM because most IEMs are autosomal recessive disorders. In addition, it should be appreciated that ordinary childhood illness is a risk factor for the presentation of IEM in an affected but previously healthy child.

## DIAGNOSIS

### Signs and Symptoms: When to Suspect Inborn Errors of Metabolism

IEMs can cause virtually any symptom or sign and can present at any age. These diseases may be static or may cause intermittent or progressive signs and symptoms. They may present commonly with intellectual disability, failure to thrive (FTT), and symptoms of septicemia. Symptoms that should particularly raise suspicion of an IEM are listed in Box 291-2.

The PCP routinely evaluates for IEMs in every healthy child through newborn screening (see Chapter 29, Screening for Genetic-Metabolic Diseases). Newborn screening is designed solely to identify neonates who need evaluation for specific conditions, and a normal newborn screen does not conclusively exclude an IEM. Physicians should maintain a high index of suspicion for an IEM because even expanded newborn screening detects only a fraction of known IEMs.

Another critical point to remember in considering a diagnosis of an IEM is that finding evidence of one condition, such as infection, does not exclude the presence of an IEM. For example, the child with a fatty acid oxidation disorder may present with acute metabolic crisis as a result of an otitis or RSV; the child may be easily diagnosed with otitis or the respiratory syncytial virus, but neither typically causes or should be assumed to explain altered mental status and abnormal liver function. Even documentation of shaken baby syndrome or other nonaccidental trauma does not exclude diagnosis of IEM because infants with underlying medical or developmental problems are at increased risk for abuse; in addition, some IEMs present with signs easily mistaken for nonaccidental trauma, such as the retinal and brain hemorrhages seen in glutaric acidemia type I.

### History and Physical Examination

When taking the history, be sure to ask about tolerance of exercise and of typically mild childhood illnesses. Also ask whether there is any association of symptoms with changes in diet or whether there are any unusual diet cravings or aversions. In addition to noting the presence of any “red flag” symptoms (Table 291-1) be aware that an IEM is more likely when there are problems in more than 1 organ or system,

### BOX 291-2 Symptoms That Raise Suspicion of an Inborn Error of Metabolism

- Altered consciousness, especially recurrent episodes of abnormal mental status out of proportion to physical health (eg, lethargy without hypoxia, shock, or meningitis); this includes altered behavior such as episodic irritability or inattention
- Seizures in the first day of life or intractable seizures
- Ataxia, especially recurrent, and any other movement disorder, especially dystonia
- Exercise intolerance with pain or fatigue that interferes with reasonable activity
- Regression in neurologic function, development or behavior, including regressive autism
- Unusual diet preferences or avoidances, eg, avoidance of protein or of certain sugars, and especially when intermittent or progressive symptoms or signs follow a diet change (eg, from breast milk to formula, or introduction of sugars)
- Odors (maple syrup, “sweaty feet,” “cat’s urine,” “mousy,” rotten fish—each suggests a specific disorder; the fruity smell of ketosis occurs in a number of conditions)
- Recurrent or persistent pain, including headaches, abdominal pain, and extremity pain
- Sun aversion or sensitivity; heat intolerance
- Family history of consanguinity or of a relative with any symptom or sign seen in inborn errors of metabolism; be aware that because most of the conditions are autosomal recessive, waiting for positive family history guarantees you will miss an opportunity to diagnose the index case in most families. Ancestry may be a clue to certain conditions.

even if there seems to be a simple explanation for each of the individual problems.

The physical signs that should particularly raise suspicion of an IEM include those listed in Box 291-3. Measure head circumference even in the older child or adolescent and examine for unusual texture of hair or unusual rashes. Pay careful attention to movement. Pay careful attention to the eyes (assessing for cloudiness or haziness), and consider an ophthalmologic evaluation to assess for the presence of these and other signs, such as retinopathy in the lens, cornea, or retina.

### Differential Diagnosis

An IEM can present with the same features as infection, neglect and nonaccidental trauma, autoimmune disorders, hypoxic ischemic injury, and poisoning. It can present with malformations leading to suspicion of nonmetabolic genetic disorders. IEM presentations overlap with many primary endocrinopathies. The features of IEMs can be thought to be the result of antecedent infection or hypoxia, whether or not there is good evidence for neonatal asphyxia or perinatal infection.

### BOX 291-3 Physical Signs That Raise Suspicion of an Inborn Error of Metabolism

- Unusual tone: Hypertonia in the neonate or hypotonia after 1 year (and certainly after 2 years) of age and mixed tone
- Movement disorders (watch carefully over at least a few minutes to see if the infant can be still for more than seconds)
- Areflexia
- Decreased muscle mass or muscle quality
- Organomegaly
- Microcephaly or macrocephaly
- Odors
- Cataracts and retinopathy
- Coarse features
- Widening of joints, kyphosis, joint contractures
- Coarse or otherwise unusual hair, unusually thick skin, unusual rashes, including sun sensitivity

In particular, if poisoning is suspected, the physician needs to consider an IEM, unless there is absolute evidence of poisoning. When there is convincing evidence for ingestion, such as an empty bottle of medications, or symptoms that perfectly match a specific toxin, such as organophosphate poisoning, it is not necessary to consider an IEM. However, because IEMs are basically a “self-poisoning,” it should otherwise be considered when poison is in the differential diagnosis. An important and instructive case is that of a woman who was tragically and inappropriately imprisoned for the murder of her child by ethylene glycol poisoning; she was released from jail when her second child was found to have the same methylmalonic acidemia that caused the death of her first son.

An IEM can mimic and coexist with child maltreatment. Two important IEMs, Menkes disease and glutaric acidemia type I, present with subdural hematoma or retinal hemorrhages, and many IEMs present with poor feeding and FTT, causing providers to consider medical neglect. However, there is also the risk that some IEMs make maltreatment more likely because of irritability and other symptoms that can make caring for the affected child more challenging.

An IEM can present acutely as a result of an infection. It is incumbent on the physician to consider whether the observed or diagnosed infection is sufficient explanation for *all* of the symptoms and signs with which the patient presents. In particular, recognize that most infections not involving the central nervous system do not cause altered neurologic status; some irritability will be typical with fever, but extreme irritability or lethargy that does not improve with resolution of fever should be a clue to an IEM. An important sign to consider as a clue to an IEM is the presence of acidosis, which should not be expected in a vomiting child unless there is severe diarrhea or poor perfusion.

The first step leading to recognition of an IEM is to include IEMs in the differential diagnosis of the child with diverse presentations. The physician then should consider the differential diagnosis within and among IEMs. The symptoms and signs across the various types of IEMs are overlapping. The specific differential diagnosis of various presentations is considered later under Clinical Scenarios in the section entitled Classification. The list of the various types of IEM in Table 291-1 includes a short synopsis of the typical clinical presentations for each category.

### Diagnostic Approach

The diagnostic approach to a child with a suspected IEM is specific to each presentation and to each condition. Although typically a collaborative effort, the physician in a nongenetics specialty can begin the process using the history—including family history—and the physical examination, followed by judicious use of laboratory studies. The diagnostic approaches are discussed in Clinical Scenarios.

### Laboratory Testing

Basic laboratory testing for an IEM can be accomplished with little added cost for the patient who has acute or chronic neurodevelopmental or health problems by starting with complete blood count (CBC), electrolytes, liver enzymes, and urinalysis in almost all cases, followed by the proper use of blood amino acid levels, urine organic acid (UOA) studies, acylcarnitine profile (ACP), carnitine total and free levels, and properly collected ammonia and lactate levels where appropriate. More specific laboratory testing can be useful.

The laboratory testing for an IEM begins with a proper interpretation of the results of testing, which is commonly done by searching for evidence of an infection and investigating the level of illness by means of CBC, electrolytes, and urinalyses. A short list of results of routine investigations, including laboratory studies that should particularly raise suspicion of an IEM, is given in Box 291-4.

For example, recognition of the inappropriateness of an increased anion gap in a vomiting child can lead to early and appropriate suspicion of an IEM. Attention to the mean corpuscular volume (MCV) may provide an important clue to an IEM as a cause of metabolic acidosis, anemia, or FTT. Judicious addition of some simple studies such as testing of creatine phosphokinase and fractionation of bilirubin can substantially strengthen the initial laboratory contribution to recognition of an IEM.

The physician should consider whether urine ketones are appropriate for the child's medical status. In the nonfasting child with FTT, positive ketones should be a clue to an IEM that produces elevated levels of an organic acid that cross-reacts with the reagent used to measure urine ketones. On the opposite end of the spectrum, absence of or low levels of ketones in the urine of the catabolic child should be recognized as a clue to an IEM that reduces ketone production. For this reason, “normal urinalysis” in a child with history of significantly decreased intake should be a clue to the possibility that the child could have a disorder of fatty acid metabolism.

**BOX 291-4 Common Test Results That Raise Suspicion of an Inborn Error of Metabolism**

- Check electrolytes and renal function; note anion gap
  - Look for acidosis out of proportion to clinical status, especially but not exclusively high anion gap acidosis; remember that renal tubular acidosis can be the result of an inborn error of metabolism (IEM)
  - Alkalosis (suspect hyperammonemia)
  - Low blood urea nitrogen (may indicate inability to make urea via the urea cycle)
- Glucose that is low in a previously healthy child with normal growth is highly suggestive of an IEM
- Check for hyperammonemia in a child with altered mental status (can only be seen if ammonia is measured); caution in sample collection
- Check urinalysis, look for inappropriate pH or ketosis
  - Ketones positive in the neonate or the nonfasting older child can indicate an IEM because the method of testing for “ketones” in urine does not distinguish between  $\beta$ -hydroxybutyrate and other organic acids such as methylmalonic or propionic acids
  - Ketones negative or only minimally increased in the infant or child who has extended fast or hypoglycemia could be because of excess insulin, liver failure, or an IEM that interferes with ketone synthesis
  - pH inappropriate for acid-base status because renal tubular acidosis can be a result of IEM
- Check complete blood count
  - Look for single or multiple failure of bone marrow cell lines
  - Look for macrocytosis (seen in disorders of energy metabolism, B<sub>12</sub> and folate metabolism, and purine-pyrimidine disorders)
- Check liver enzymes for evidence of liver dysfunction
  - Consider whether to fractionate the bilirubin
  - Consider testing prothrombin time and ammonia because they are true measures of liver function, not just liver inflammation
- Look for evidence of pancreatitis
- Consider testing creatine phosphokinase that could be evidence of rhabdomyolysis
- Consider echocardiogram for cardiomyopathy (especially hypertrophic and arrhythmogenic right ventricular dysplasia)
- Look for dysrhythmia in neonate, triphasic waves, or any electroencephalogram described as having abnormal background
- Examine magnetic resonance imaging for white matter disease, including stroke and periventricular leukomalacia in absence of clear history of asphyxia or clot
- Consider magnetic resonance spectroscopy for lactate, creatine, or other appropriate metabolites
- Consider routine radiography in a patient with rickets with normal vitamin D or in a patient with stippled epiphyses or dysostosis multiplex

When an IEM is suspected and the physician is considering specific testing to narrow the differential diagnosis, it is critical to be aware that some test results depend on the status of the patient. Biochemical samples collected while the child is acutely symptomatic may be diagnostic, whereas samples for the same study collected between episodes may be normal in some conditions and some patients. This is especially true for some disorders of organic acids, amino acids, urea cycle, mitochondrial conditions, fatty acid oxidation, and some porphyrias. Therefore diagnostic samples should be collected promptly on presentation of a symptomatic child. Normal results can only exclude a diagnosis if the sample were collected under appropriate circumstances. Artifacts of sample collection are particularly problematic for some tests, most particularly lactate and ammonia (see the accompanying Box 291-5, and for details see Table 291-2). Attention to proper sample collection is critical for interpretable results.

For some IEMs, the informative studies require an analysis of cerebrospinal fluid (CSF) or of tissue, such as muscle, for the measurement of appropriate analytes or for enzyme assay. It is therefore important to consider IEM sufficiently early in the process of evaluation that an appropriate sample can be collected if invasive testing is planned or performed. For example, when a lumbar puncture is considered to evaluate for a possible chronic infection or new-onset afebrile

**BOX 291-5 Focused Testing for Inborn Errors of Metabolism**

- If not already done and if clinically indicated, check for hyperammonemia
- Lactate and pyruvate: Do *not* send child to laboratory or request sample to be collected by phlebotomy because sample collection and handling errors can cause significant problems with interpretation.<sup>a</sup> Lactate and pyruvate should be evaluated, when indicated, under controlled circumstances, ideally in the fasting individual (levels rise with consumption of any sugar, especially fructose), without any struggle (lactate levels rise with muscle activity), and with no tourniquet (lactate levels rise and pyruvate levels fall as pyruvate is converted to lactate in the anaerobic environment)
- Blood amino acids (plasma or serum in accordance with preference of the laboratory that will receive the sample)
- Organic acids
- Acylcarnitine profile
- Carnitine total and free
- Mucopolysaccharides or glycosaminoglycans in urine

**Table 291-2**      **Specific “Metabolic” Testing**

<p><b>Ammonia</b> Typically green-topped tube (do <i>not</i> use ammonia heparin tube), free flowing and placed on ice and hand-carried to laboratory. However, each institution’s laboratory has specific instructions.</p>	<p>Hyperammonemia is not evident on physical examination. Most accurate if collected without a tourniquet and couriered immediately to laboratory on ice because levels rise in the test tube until the sample is spun. Levels near or above 200 (sometimes 150 <math>\mu\text{mol/L}</math>) cause brain cell dysfunction and may cause cerebral edema; brain damage is universal and typically irreversible after 3 days of ammonia at levels greater than 200 <math>\mu\text{mol/L}</math>. Urea cycle defects may cause levels in the thousands of micromoles per liter. Hyperammonemia is an emergency; dialysis may be needed urgently, and specific drugs are available for “chemical dialysis.” Although ideally collected properly, if an inappropriately collected level is normal, it excludes hyperammonemia as cause of coma; if it is markedly elevated, it is unlikely to be an artifact, and if it is mildly elevated, an immediate repeat sample collected properly should clarify the situation because ammonia does not change rapidly without specific therapy. The level of ammonia will not necessarily distinguish urea cycle defects from organic acidemias, although the latter are more often associated with metabolic acidosis and an elevated anion gap.</p>
<p><b>Lactate (and pyruvate)</b> Ideally special tube that hydrolyzes all protein, free flowing and placed on ice and hand-carried to laboratory. However, each laboratory has specific instructions.</p>	<p>Exquisitely sensitive to conditions of the patient and the sample collection; lactate levels can change in minutes with changes in blood pressure and perfusion and with changes in intravenous glucose. Normal values are available for fasting and resting individuals. Nevertheless, lactate levels are useful in the emergency setting and elevations out of proportion to clinical status may provide clue to a wide variety of IEMs. Lactate-to-pyruvate ratio is altered in some patients with mitochondrial disease, in the same direction as the alteration of the ratio in hypoxia or hypoperfusion. Lactate levels should always be collected and handled properly.</p>
<p><b>Blood AA</b> Typically written PAA for plasma AAs (green top), but some laboratories prefer serum (red or tiger top).</p>	<p>Laboratories that perform the test will have preference for either plasma or serum; however, if your sample is not of the preferred type, contact the biochemical laboratory directly because they will typically be able to analyze the sample. The laboratory also typically is able to perform the test on a sample smaller than that routinely requested for adults. Testing may also be done in some laboratories on filter paper. AA can also be tested in other body fluids, most commonly urine and CSF, but metabolic autopsy testing can be done on vitreous of the eye or on renal papilla. AAs are conserved (reabsorbed) in the kidney so that blood analysis is useful for most conditions, but UAA analysis is key to diagnosis of conditions in which dysfunction of renal absorption of AA is the disorder. Laboratories will provide not only an interpretation but also the specific levels; an intermediary laboratory often will provide only the interpretation. The specific levels are needed to calculate the ratio of alanine to lysine, useful in evaluation of disorders of energy metabolism.</p>
<p><b>OA</b> Typically written UOA for urine OA; typically a random sample</p>	<p>Typically measured in urine because most OAs are toxic compounds that are poorly reabsorbed by the renal tubule, but some laboratories can perform limited testing on blood in anuric patients. Laboratories can typically perform testing on small samples. For acutely ill patients, samples are ideally collected at presentation before any therapies that affect metabolism.</p>
<p><b>ACP</b> Most laboratories request green top for plasma, some prefer serum (red or tiger top), and some can analyze filter paper.</p>	<p>An analysis of markers that indicate what compounds are bound to carnitine. This is <i>not</i> the same as a “carnitine profile.” This is the preferred test for diagnosis of most disorders of fatty acid oxidation and is useful in many organic acidemias. For acutely ill patients, ideally collected at presentation before any therapies that affect metabolism. Often analyzed using the same methods that are used in newborn screening, but normal newborn screen does not substitute for ACP analysis in the symptomatic patient.</p>
<p><b>Carnitine total and free</b> Most laboratories request green top for plasma, some prefer serum (red or tiger top), and some can analyze filter paper.</p>	<p>A measurement of the levels of free carnitine (that which is available for transport of fatty acids into the mitochondria) and of bound carnitine. It is <i>not</i> the same as ACP. It is particularly useful for diagnosis of disorders of carnitine transport and is secondarily abnormal in many fatty acid oxidation disorders, organic acidemias, and some nutritional states.</p>

**Table 291-2** Specific “Metabolic” Testing—cont’d

Neurotransmitters Typically CSF, <i>requires special handling</i>	Some neurotransmitters can be measured in blood or urine, but certain conditions can only be identified by analysis of CSF. There is a rostrocaudal gradient of neurotransmitter levels in the CSF, and therefore to be interpretable, the laboratory requires that the sample for neurotransmitters be collected in special tubes and that the sample collection begin with the first drop of fluid—before measurement of pressure or collection of fluid for culture (the “special” tubes are also needed to prevent oxidation of some metabolites). CSF analysis for neurotransmitters therefore requires anticipation of collection and collaboration with appropriate specialists and with the local and reference laboratories.
